The genetics of type 2 diabetes

Emma Ahlqvist[1] and Leif Groop[1,2]
[1] Department of Clinical Sciences, Lund University, University Hospital Skåne, Malmö, Sweden
[2] Finnish Institute for Molecular Medicine (FIMM), University of Helsinki, Helsinki, Finland

> ## Key points
>
> - The risk of developing type 2 diabetes depends on both environmental and genetic factors but their relative importance in the general population is difficult to determine.
>
> - The genetic architecture of T2DM is complex and mostly unknown but involves a large number of genetic risk variants of which more than 75 have been identified.
>
> - Most loci so far have been identified in genome-wide association studies. The risk variants are common in the population, have only a small effect on disease risk and together only explain a fraction of the heritability of the disease.
>
> - Recent advances in sequencing technology now allows whole genome/exome sequencing in larger cohorts which may enable identification of rarer variants with stronger effects.
>
> - The missing heritability not explained by the hitherto identified loci could be due to yet unidentified common variants, rare variants, gene–gene or gene–environment interactions or epigenetic effects.

The diabetic spectrum

Diabetes is a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both. The chronic hyperglycemia of diabetes is associated with long-term damage, dysfunction, and failure of different organs, especially the eyes, kidneys, nerves, heart, and blood vessels.

There are several types of diabetes with differing disease mechanisms and clinical characteristics (Figure 26.1). Type 2 diabetes (T2DM) is the most common form, constituting 80–90% of all diabetics. T2DM develops when pancreatic β-cells can no longer increase their insulin secretion enough to compensate for increasing insulin resistance imposed by increasing obesity. There is no formal definition of T2DM; instead diabetes patients who do not fulfill the criteria of any other form of diabetes (see later) are considered to have T2DM. While T2DM onset is usually after the age of 35, it is not uncommon that T2DM is diagnosed already in adolescents in high-risk regions such as Asia, the Middle East, and USA.

Type 1 diabetes (T1DM) affects ∼8% of diabetes patients and is due to autoimmune destruction of pancreatic β-cells and is characterized by complete lack of insulin secretion, presence of autoantibodies to glutamic acid decarboxylase (GAD) and, usually, onset of disease before age 35. LADA (latent autoimmune diabetes in adults) accounts for about 7% of all diabetic patients in Europe and is usually defined as GAD antibody-positive diabetes with onset greater than 35 years of age [1]. These disease types could be divided further into subtypes possibly representing different disease mechanisms. In addition there are less common diabetes types including MODY (maturity onset diabetes of the young), representing a monogenic form of diabetes with well-defined mutations in more than six different genes, as well as neonatal and secondary diabetes. These forms of diabetes represent a range of genetic etiologies from the monogenic MODY variants to T2DM, which is a highly complex multigenic disease with a very strong environmental component.

The diabetes epidemic

Worldwide prevalence figures estimate that there were 371 million diabetic patients in 2012 and more than 500 million are expected in 2030 (www.diabetesatlas.org). In Europe, ∼ 8% of the population suffer from diabetes and up to 90% of these have T2DM, making this the fastest increasing disease in Europe and worldwide. The T2DM epidemic can largely be ascribed to the worldwide increase in obesity during the last 30 years, for example more than 60% of individuals older than 15 in the UK and US are overweight (BMI > 25). This in turn has been ascribed to a collision between genes and the environment. In a situation of affluence most people tend to overconsume
Figure 26.1 The spectrum of diabetes subgroups. The data is from the ANDIS project (All New Diabetics in Scania) (http://andis.ludc.med.lu.se) in April 2014 which at that time included 9800 newly diagnosed diabetic patients aged 0–100 years. The criteria used for diagnosis are as follows: T1DM: age at onset <35 years, C-peptide <0.2 nmol L^{-1} and GAD antibodies >20; T1DM with relative insulin deficiency if C-peptide 0.2–0.6 nmol L^{-1}. T2DM: age at onset >35 years, C-peptide >0.6 nmol L^{-1}, GAD antibodies <10; T2DM with relative insulin deficiency C-peptide 0.2–0.6 nmol L^{-1}. LADA (latent autoimmune diabetes in adults): age at onset >35 years, GAD antibodies >20; LADA light if GAD antibodies 10–20. Source: Data from the ANDIS project (All New Diabetics in Scania) (http://andis.ludc.med.lu.se).

calories and gain excess weight. One possible reason for this is that genetic selection has favored energy-preserving genotypes (so called thrifty genotypes); individuals living in an environment with unstable food supply could maximize their probability of survival by efficiently storing energy in times of surplus [2]. While this hypothesis provides an appealing explanation to the obesity and T2DM epidemic, formal proof for this hypothesis is still lacking.

Heritability of T2DM

It has long been clear that T2DM clusters in families and it is well established that the risk of developing T2DM depends on both genetic and environmental factors. However, the exact proportion of the two, that is, the heritability, is difficult to determine and heritability estimates therefore vary in the range of 25–80% between studies. Twin-studies have estimated the genetic component by comparing disease concordance in dizygotic twins with concordance in monozygotic twins. In these studies probandwise concordance rates (number of affected twins having a diabetic co-twin) for monozygotic twins vary between 34 and 100% [3–6].

The relative risk for first-degree relatives, that is, the risk of developing T2DM if you have an affected parent or sibling compared to the general population, is approximately 3, and ~6 if both parents are affected [7]. However, this statistic also varies depending on the cohort and population studied.

There are also large differences between ethnic groups that seem to depend on genetic factors. The prevalence of T2DM varies widely among populations, from a few percent among Caucasians in Europe to as high as 50% among Pima Indians in Arizona [8]. While part of the observed ethnic variability could be attributed to environmental and cultural factors some of the variation seems to depend on genetic differences.

One limitation of both twin and family studies is that they have a risk of overestimating heritability due to sampling and ascertainment errors. Concordant twins are more likely to participate in a study and the proportion of individuals with undiagnosed diabetes may differ compared to the general population. Also, the families recruited to genetic studies may represent a subset of highly heritable T2DM whereas an outbred population could have more sporadic or environmentally induced cases.

Another limitation is that family studies often cannot distinguish between the effect of genetic inheritance and the effects of a shared environment and the gene–environment correlation that comes from nongenetic inheritance. This problem could be especially large in T2DM since poor eating and exercise habits are often part of the social inheritance and strongly affect diabetes risk.

Another interesting fact is that the risk of T2DM is higher in individuals who have an affected mother, compared to an affected father [9]. There are many possible explanations for this including a role for the intrauterine environment in programming events later in life. Intrauterine effects can also affect heritability estimates because monozygotic twins are often monochorionic, which results in growth retardation compared to dizygotic twins, and low birth weight is associated with increased risk of T2DM later in life.

In spite of these reservations, there is no doubt that the risk of T2DM is partly determined by genetic factors, many of which have already been identified, and while each identified variant explains only a very small proportion of the risk of T2DM in the human population they all contribute to our understanding of disease pathogenesis. One should also keep in mind that the variance explained by a risk allele in a population is not necessarily an indicator of its importance in specific patients, nor is it proportional to the affected pathway's importance or potential as a therapeutic target.

Identification of T2DM affecting genetic variants

Linkage studies

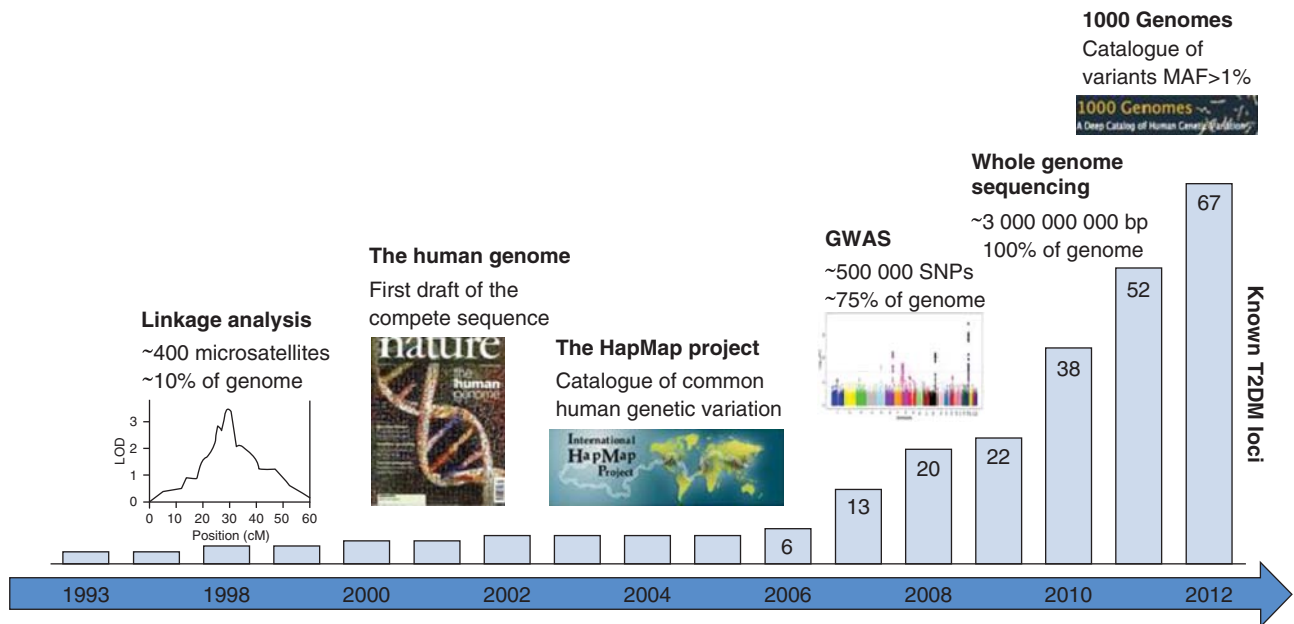
The methods used to map disease-causing variation have evolved rapidly in the last decades thanks to technical advances in genotyping methods (Figure 26.2). Originally, disease-causing loci were identified primarily by linkage analysis, utilizing the long stretches of linkage in affected families. By genotyping 400–500 genetic markers, disease loci can be mapped on a genome-wide level without any prior hypothesis


Figure 26.2 The evolution of genetic mapping methods used to identify T2DM loci. The bars show the growth in number of known loci year by year with a very slow progression until the implementation of GWAS in 2007. For loci identified by whole-genome association only loci reaching genome-wide significance ($p < 5 \times 10^{-8}$) are included.

about which genes are involved. Finding that affected family members share a certain marker that is identical by descent (i.e., identical because it was inherited from the same parent) more often than expected by chance is evidence that a disease-causing variant is in linkage with that marker. This strategy has been very successful in mapping genetic diseases like MODY that have a strong penetrance and a known mode of inheritance. The first MODY locus, MODY-2, was mapped to the glucokinase (*GK*) locus on chromosome 7 in 1992 [10]. It was soon followed by the *HNF1A* (MODY-3) and *HNF4A* (MODY-1) loci [11,12]. The HNF homeobox genes are transcription factors expressed in liver and β-cells that are necessary for proper regulation of insulin secretion. Common variants in both these loci have since been shown to affect risk of T2DM [13].

Linkage analysis has, however, been less useful for identifying genes causing complex diseases. Even though great efforts have been put into linkage studies of T2DM, only two genes can be claimed to have been identified using this strategy. The first T2DM gene mapped by linkage analysis was *CAPN10* on chromosome 10, encoding calpain 10, a cysteine protease with largely unknown functions in glucose metabolism [14]. Despite a number of negative replication studies, several meta-analyses have shown consistent association with T2DM [15,16]. Nevertheless, none of the large genome-wide association studies (GWAS) have identified *CAPN10* as being associated with T2DM.

The second locus was first mapped to a 10.5 Mb region on chromosome 10q and was later fine-mapped in the Icelandic population to an intronic variant in the *TCF7L2* gene contributing to, but not fully explaining, the original linkage

[17–19]. This association has since been confirmed in African, Asian, and European populations making it the best replicated genetic association with T2DM to date, conferring a relative risk of ~1.4 [20].

Association studies on candidate genes

A popular hypothesis about the genetic architecture of complex diseases such as T2DM, the common disease/common variant hypothesis, suggests that common disorders are caused by aggregation of common risk alleles [21,22]. This model has been the basis of a revolution in complex genetics by stimulating the development of tools for genetic association studies. Association studies utilize the very short LD stretches in unrelated individuals to map risk variants in populations instead of families. The advantages of association lie in the larger number of individuals that can be collected for each study as well as the much higher resolution of the mapping. One disadvantage is the huge number of markers needed to perform mapping on a genome-wide level and association studies were therefore originally performed on small regions known to harbor candidate genes.

The first gene reproducibly associated with T2DM was *PPARG*, encoding the nuclear receptor PPAR-γ [23]. The PPAR-γ receptor is a molecular target for thiazolidinedione compounds, a class of insulin-sensitizing drugs used to treat T2DM, making it a very compelling candidate gene. The transcript expressed in adipose tissue has an extra exon B and a substitution of a proline for alanine at position 12 of this protein, which is seen in about 15% of the European population. This variant, has been shown to be associated with

increased transcriptional activity, increased insulin sensitivity, and protection against T2DM [23].

The *ADRA2A* (adrenergic receptor alpha 2) locus was recently identified as a T2DM risk locus after first having been positionally mapped in congenic GK rats where it was associated with impaired insulin granule docking and reduced β-cell exocytosis [24]. Human carriers of the *ADRA2A* risk variant (rs553668) have reduced fasting insulin and decreased insulin secretion as a consequence of increased expression of the ADRA2 receptor in pancreatic islets. It is well known that epinephrine excess can suppress insulin secretion and cause diabetes.

Genome-wide association studies (GWAS)

Rapid improvement in high throughput technology for SNP genotyping, allowing simultaneous genotyping of hundreds of thousands of SNPs, has opened new possibilities for association studies. The HapMap project provided another important tool, showing that genotyping of approximately 500,000 SNPs is enough to cover about 75% of the common variants (minor allele frequency >5%) in the genome. Several GWAS for diabetes were published in 2007, coined "Breakthrough of the Year" by *Science* magazine. The first was a GWAS on early-onset T2DM that was published in February 2007 reporting two new diabetes loci: *HHEX* and *SLC30A8* [25]. A few months later it was followed by four European case-control studies including patients with classical T2DM [26–29]. Three of the studies shared results prior to publication and only considered positive results that were replicated in all studies. This resulted in the identification of two new diabetes loci, *CDKN2A/2B* and *IGF2BP2*, in addition to confirming previously known loci. *CDKAL1* (CDK5 regulatory subunit associated protein 1-like 1) was independently identified as a new T2DM locus in all four studies.

About the same time *FTO* was identified as a major susceptibility locus for obesity, and therefore indirectly also for T2DM [30,31]. Since the effect of *FTO* on diabetes is through obesity it was not detected in the GWAS studies of T2DM that were matched on BMI.

The first GWA studies on T2DM in non-European populations were published in 2008 using a multistage approach [32,33]. Both studies identified *KCNQ1*, which encodes the pore-forming alpha subunit of the I_{Ks} K$^+$ channel (or voltage-gated potassium channel), and showed that the gene is expressed in the pancreas. Later a SNP in *KCNQ1* was shown to have distorted parent-of-origin transmission in an Icelandic study, the risk allele having a much stronger effect when transmitted from the mother than from the father [34].

The first wave of GWAS was followed by a second wave combining existing or new GWAS into meta-analyses of >50,000 individuals [13,35]. A prerequisite for this was that many research groups could work together in consortia like DIAGRAM (DIAbetes Genetics Replication and Meta-analysis) consortium and MAGIC (Meta-Analyses of Glucose- and Insulin-related traits consortium). These very large studies have identified several new loci and confirmed the effect of many previously identified. This has also been facilitated by the 1000 Genomes Project, another international collaboration to produce a public catalog of human genetic variation, including SNPs and structural variants, which now allows imputation and analysis of more than 30 million common and low-frequency variants.

Recently, a number of GWAS and meta-analysis studies have also been performed in non-European cohorts, adding several new loci to the list of genome-wide significant associations [35–45]. Interestingly it seems like most associations found in one ethnic group also show some evidence of association in populations with other ethnicities. In total, GWAS have provided more than 75 loci for T2DM (Table 26.1) as well as numerous loci for glucose- or insulin-related traits and more are likely to come.

High density mapping

GWAS do not inevitably lead to identification of a gene or genes in a given locus associated with disease. The most strongly associated SNPs are often only markers for the functional variant responsible for the observed genetic effect and most associated regions harbor several genes. Therefore, additional fine mapping of the loci in even larger sample sets is often necessary. To do this cost-efficiently a Cardio-Metabochip has been developed for metabolic/cardiovascular gene mapping. This custom-design Illumina Infinium genotyping chip contains ~200,000 polymorphisms selected to cover association signals from a wide range of metabolic disorders (T2DM, lipid disorders, obesity, and cardiovascular disease), was designed to perform both deep replication of major disease signals and fine mapping of established loci. Meta-analysis of previous GWAS with an additional 22,669 T2DM cases and 58,119 controls genotyped using the Cardio-Metabochip has recently added another eight new loci associated with T2DM in the European population [46].

Next-generation sequencing will provide even denser coverage of genetic variation. Scientists in Iceland recently identified four new rare and low-frequency variants (minor allele frequency 0–5%) associated with T2DM through whole-genome sequencing of 2630 Icelanders and imputation of genotypes in more than 290,000 closely related individuals [47]. The GoT2D consortium aims to map lower frequency variants via low-coverage whole-genome sequencing, deep exome sequencing, and next-generation 2.5M SNP chip genotyping of 1325 cases and 1325 controls selected in the phenotype extremes of T2DM. A custom-designed Exome Chip containing rare variants that have been seen at least three times in different studies has also been designed and is currently used to try to identify rare variants associated with T2DM.

Functions of associated genes

Most identified diabetes loci have not been mechanistically tied to the disease. While loci are commonly referred to by the

R/NR, risk/nonrisk allele; RAF, risk allele frequency in HapMap CEU individuals with risk allele frequency in reference study for non-Europeans.
[a]In the discovery article RAF for the European population is stated as 0.31.

names of candidate genes located close to them, only a few are close to strong biologic candidates, including the melatonin receptor (MTNR1B) and the insulin receptor substrate-1 (IRS1). For others, like *TCF7L2* and *GIPR*, the evidence is quite strong that an intronic SNP is the causal SNP. Melatonin receptor 1B (*MTNR1B*) has been found to be associated with both fasting glucose and T2DM risk [48–50]. Melatonin works as a chronobiotic factor, adjusting the timing of the biologic clock. Its receptors are present in the pancreas and melatonin is proposed to contribute to the nocturnal lowering of insulin in humans. The *MTNR1B* risk genotype is associated with impaired early insulin release to both oral and intravenous glucose and insulin secretion deteriorates over time in the risk allele carriers [48]. The proposed mechanism by which *MTNR1B* polymorphism could predispose to T2DM involves altered expression of MTNR1B in pancreatic β-cells leading to decreased cAMP/cGMP concentrations via G proteins and, thereby, impaired insulin secretion.

The insulin receptor substrate 1 (*IRS1*) gene encodes a protein that mediates insulin's control of various cellular processes by transmitting signals from the insulin receptor to intracellular signaling pathways. The C allele of rs2943641 has been shown to be associated with insulin resistance and increased risk of diabetes. The genetic variant causes reduced basal levels of IRS1 protein and decreased insulin induction of IRS1-associated phosphatidylinositol-3-hydroxykinase activity in human skeletal muscle biopsies [51].

TCF7L2 is a transcription factor playing an important role in the Wnt signaling pathway. The risk allele is associated with decreased insulinogenic index and lower disposition index, suggesting a reduced capacity for insulin secretion in relation to insulin sensitivity. Since it was identified as a diabetes gene it has been shown to be important for several vital functions in the pancreatic islet, including pancreas development, determination of β-cell mass, and maintenance of the secretory function of mature β-cells.

The incretin hormone GIP (glucose-dependent insulinotropic polypeptide) promotes pancreatic β-cell function by potentiating insulin secretion and β-cell proliferation. The GIP receptor (*GIPR*] locus showed association to postprandial insulin levels in a meta-analysis performed by the MAGIC consortium but was surprisingly not associated with risk of diabetes in the DIAGRAM+ study [13,52]. The reason seems to be that the same variant results in decreased BMI, which neutralizes the effect of the SNP on risk of T2DM. GIP influences expression of the inflammatory cytokine OPN in islets and fat, which in turn, has protective effects on β-cell proliferation and potentially apoptosis, but detrimental effects on insulin sensitivity [53,54].

Many of the other recently identified loci can be subgrouped based on their association with other phenotypes with a key role in T2DM etiology. Exploration of the effects of T2DM-associated variants on glucose and insulin traits in nondiabetic populations has shown that most of the known loci act through an effect on insulin secretion rather than insulin resistance (Table 26.1) [13,24,55,56].

Fasting glucose-raising alleles of the *MADD*, *GIPR*, *GCK*, *FADS*, *DGKB*, *PROX1*, *TCF7L2*, *SLC30A8*, HHEX/IDE, CDKAL1, CDKN2A/2B, and *C2CD4B* loci have all been associated with either abnormal insulin processing or secretion whereas *GCKR* and *IGF1* are associated with OGTT-based disposition indices and β-cell function [55,57]. The DIAGRAM+ consortium observed that three loci (*TCF7L2*, *ARAP1*, and *CDKAL1*) were associated with reduced fasting insulin also suggestive of β-cell dysfunction, whereas the T2DM risk alleles at *PPARG*, *FTO*, *IRS1*, *GCKR*, and *KLF14* were associated with higher fasting insulin, indicating a primary effect on insulin action [13,57].

The missing heritability

In spite of the large number of risk variants identified, it is estimated that they explain less than 15% of the heritability of T2DM. The unexplained heritability is an intensely discussed topic in complex genetics, some claiming it as a failure of GWA studies. There are many possible explanations for the missing heritability, including assumptions made about the genetic architecture of the disease and the definitions of heritability. The estimations of heritability explained assumes that only additive affects determine disease risk and that the risk follows the liability threshold model, that is, the genetic and environmental effects sum up to form a normal distribution of liability and that disease arises in individuals surpassing a certain threshold in the distribution [58]. If these assumptions are not true, the estimate of heritability explained will not be correct. However, there are also many other potential explanations for the missing heritability: yet unmapped common variants, distorted parent-of-origin transmission of risk alleles, rare variants, structural polymorphisms (e.g. copy number variations), gene–gene and/or gene–environment interactions (in which epigenetic effects may be important).

The genetic architecture of T2DM

There is an ongoing debate about the genetic architecture underlying common complex diseases. Some argue that disease risk is determined by a large number of very small additive effects from relatively common variants and that disease represents the extremes of a normal distribution [59] while others argue that complex diseases are rather collections of phenocopies caused by rare, often recent, mutations [60]. One argument against common variants is that they would have been removed from the population by natural selection [8]; however, this is not a valid argument for a disease like T2DM where the penetrance of the genetic effect depends strongly on interactions with the environment, especially since this environment has changed in recent years and the genetic risk variants could have been neutral or even beneficial before the

introduction of the Westernized lifestyle. Applying an approach that considers all SNPs in a GWAS could in fact explain a much larger proportion of the heritability (>50%) supporting the existence of numerous yet unidentified loci with smaller effects [13,61]. However, one should keep in mind that heritability can only be estimated from the most recent generations for which information on affection status is available, whereas most of the variants studied thus far are ancestral variants hundreds of generations old. We do not know whether these ancestral variants (which have modest effects and have escaped purifying selection) can really explain the diabetes epidemic we see in the most recent generations or whether this can be ascribed to rare variants with stronger effects. The truth may thus rather be a combination of the suggested models, at least for T2DM.

The genetic architecture could also vary within the T2DM patient group since the diagnosis may include cases of disease caused by rare, or even unique, variants with high penetrance, in parallel or combination with cases pushed over the disease threshold by their load of common risk alleles. Allelic heterogeneity can also be expected at any single disease locus, that is, there may be multiple, different susceptibility mutations at the locus conferring risk in different individuals and both common and rare variants could contribute to disease susceptibility similar to what has been found at the *HNF1A* and *HNF4A* MODY loci. Structural polymorphisms and microRNAs add a further layer of complexity and have not yet been exhaustively studied.

The rapid development of next generation sequencing tools has markedly facilitated discovery of rare variants. From being both extremely expensive and effort consuming, sequencing of the whole genome with appropriate coverage (approx. 30 times) can now be performed for <$1000 in a few days. Whole-exome sequencing can be performed for less than $400 per sample and these figures are likely to decrease over the coming years. Applying these methods in families and large population studies will hopefully answer the questions about the role of rare variants in complex diseases.

Most studies to date have been limited to SNP leaving structural polymorphisms relatively unexplored. However, since common structural variants are likely to be tagged by surrounding SNPs they are unlikely to explain a large proportion of missing heritability. A recent study [62] identified a common copy number variation (CNV), CNVR5583.1 (*TSPAN8*), as associated with T2DM. This association could be convincingly replicated by previously typed SNPs that tag the CNV [63].

Noncoding RNAs have recently emerged as important regulators of gene expression and function. MicroRNAs (miRNAs) naturally regulate programs of gene expression. Altered miRNA function has been shown to contribute to human disease, and manipulation of specific miRNAs is now being explored as a novel therapeutic modality [64]. The efficiency of miRNAs binding to target transcripts depends on both the sequence and the intramolecular structure of the transcript. SNPs can contribute to alterations in the structure of regions flanking them,

thereby influencing the accessibility for miRNA binding. Several studies have implicated miRNAs in diabetes and inflammation and common SNPs change the target sequence of miRNAs in several T2DM susceptibility loci [65,66]. Other forms of noncoding RNAs, such as piRNAs (PIWI-interacting RNAs), snoRNAs (small nucleolar RNAs), lincRNAs (long intergenic noncoding RNAs), and lncRNAs (long noncoding RNAs), may also contribute to the development of diabetes. For example, the CDKN2A/B region on chromosome 9 is associated with T2DM, as well as cardiovascular disease and a number of other disorders. This region harbors an lncRNA, ANRIL (nonprotein coding CDKN2B-AS1 CDKN2B antisense RNA 1), which can potentially modify and explain some of these associations [67].

Gene–gene and gene–environment interactions

Gene–gene interactions, or epistasis, have been suggested as a possible explanation for difficulties in replicating genetic association in complex diseases [68]. The standard statistical methods used in association studies are usually limited to analysis of single marker effects and thereby do not account for interactions between markers. Previous attempts to study epistasis in complex diseases have focused on interactions between candidate regions [69,70]. However, the recent abundance of GWAS data has made a comprehensive search across the genome more feasible. Some studies have attempted to account for epistasis in GWAS using a two-step approach in which significant SNPs are tested against each other or against all other SNPs in the study with variable results [71,72]. The main problem when studying epistasis is power, since interaction between loci with modest effects is difficult to detect without extremely large sample sizes. However, a study using simulated data has shown that power could actually increase when testing all pair-wise combinations of SNPs in GWAS settings despite the penalty for multiple testing; especially when no marginal effects were present [73]. Thorough studies in diabetes addressing epistasis using this approach are missing.

Further, a recent paper by Eric Lander and coworkers provided compelling evidence that gene–gene interaction can also contribute to missing heritability by causing "phantom heritability" that inflates the estimated narrow sense heritability of the trait [74].

Gene–environment interactions are equally difficult to study but are likely to play an important role in T2DM development. The epidemic of T2DM only dates back 50 years, and it is quite obvious that during this period only the environment, not the genes have changed. However, the genetic architecture determines our response to the environment. Genetic variants could affect specific metabolic processes to make an individual more susceptible to the harmful effects of a poor diet but also personality traits that make an individual more or less likely to overconsume and live a sedentary lifestyle. It will however be a formidable task to identify the environmental triggers for most of the genetic variants increasing susceptibility to diabetes as

this will require very large studies with precise information on diet, exercise, energy expenditure, and so on.

Epigenetics

The environment can also influence the expression of the genome, and ultimately the phenotype, via the epigenome. Even though the DNA sequence is not changed, the phenotype is altered by epigenetic modifications of gene expression by mechanisms including methylation of DNA, posttranslational modification of histones, or activation of microRNAs. These modifications have the potential to be stable and heritable across cell divisions [75,76]. Changes to the phenotype can be at the level of the cell, tissue, or whole organism.

It is tempting to speculate that environmental factors such as diet and exercise can change the level of DNA methylation and thereby cause changes in gene expression, but evidence that DNA methylation contributes to the increase in T2DM is still lacking. Epigenetic mechanisms may, however, play a role in progression of the disease by inducing glucotoxicity in islets and predispose to diabetic complications. Elevated glucose is a prerequisite to this condition and it is well established that cells can memorize changes in glucose concentrations. For example, two large studies, the UKPDS and DCCT studies, showed that an initial good metabolic control was associated with reduced frequency of diabetic complications decades later. The advanced "metabolic memory" hypothesis suggests that this is because glucose can induce histone modifications in endothelial cells that can be remembered long after [77].

As previously mentioned, the risk of T2DM in offspring is greater if the mother has T2DM compared to if the father is affected. The reasons for this parent-of-origin effect are unknown but one potential explanation could be distorted parent-of-origin transmission of risk alleles which is often associated with DNA methylation and imprinting. Variants in both *KCNQ1* and *KLF14* show stronger effects on T2DM when the risk allele is transmitted from the mother than from the father [34,78]; in some instances the paternal allele can even be protective making it almost impossible to detect association in a traditional case-control study.

Epigenetic mechanisms can also act *in utero*. If this intrauterine programming results in a reduced β-cell mass, it could predispose to diabetes later in life when the insulin requirements increase as a consequence of obesity and insulin resistance.

Systems biology

GWAS on their own provide limited insights into the molecular mechanisms driving disease. To reach an understanding of disease pathogenesis, it is important to analyze the GWAS data in the context of complementary types of follow-up analyses such as related protein module analysis, expression profiling under conditions relevant for the disease, and analysis of genotype-phenotype associations [79]. For example, by combining GWAS information with metabolomics it has been possible to identify strong associations between SNPs

and metabolic reactions that otherwise would have been missed [80]. Network or pathway-based approaches, including enrichment in pre-defined pathways by, for example, KEGG [81] (www.genome.jp) and Gene Ontology (GO) (www.geneontology.org), have also been used to identify disease genes for various diseases [79,82–85]. Thus, an integrative approach of several data types is likely to discover disease genes that would not be identified by the use of classical GWAS approaches. This was also illustrated in a recent study of human islets identifying novel candidate genes for T2DM based upon expression differences and co-expression with known T2DM genes as well as protein–protein interaction analyses [86]. Integration of GWAS data with such data could, thus, facilitate a systems-based understanding of the pathogenic mechanisms.

Conclusions

The technical revolution in the field of genetics has allowed identification of numerous genetic variants that associate with T2DM. Yet, the dissection of the genetics of T2DM is still in its infancy, so far only explaining a small proportion of the total heritability of diabetes. In spite of this, it has already greatly contributed to our understanding of disease mechanisms by identifying pathways that could not be linked to diabetes by existing hypothetical models, even though many genetic findings are very recent and have yet to make their contribution to our knowledge about diabetes pathogenesis. Diabetes is probably a much more diverse disease than the current subdivision into T1DM and T2DM implies and a more precise subdivision into subgroups may both facilitate the investigation of T2DM genetics and pave the way for more individualized treatment. A holistic systems biology approach will also be required to obtain a complete picture of how genetic variation leads to diabetes. The rapid technology development during the past years holds promises that this will be possible in a not too distant future.

CHAPTER 27

Glucose toxicity

Hannele Yki-Järvinen[1] and Donald A. McClain[2]

[1] Department of Medicine, University of Helsinki, Minerva Foundation Institute for Medical Research, Helsinki, Finland
[2] Department of Medicine, University of Utah and Veterans Affairs Medical Center, Salt Lake City, UT, USA

Key points

- Acute hyperglycemia increases glucose utilization (mass-action effect of glucose).
- Chronic hyperglycemia impairs glucose utilization ("glucose toxicity").
- Acute hyperglycemia stimulates insulin secretion.
- Chronic hyperglycemia impairs insulin secretion ("glucose toxicity").
- The rate of glucose utilization is decreased in type 1 and type 2 diabetic patients when studied under normoglycemic conditions but normal when measured under hyperglycemic conditions.
- Any intervention, which improves glycemic control, improves insulin sensitivity and insulin secretion.
- The hexosamine pathway has been convincingly linked to glucose-induced insulin resistance and β-cell failure.
- The hexosamine pathway metabolizes a small fraction of glucose to UDP-N-acetylglucosamine, which responds to increased cellular glucose flux in insulin-dependent tissues by downregulating insulin-stimulated glucose uptake.

Introduction

Several studies, culminating in the large and definitive Diabetes Control and Complications Trial and the United Kingdom Prospective Diabetes Study [1,2] have established that hyperglycemia is the major risk factor for microvascular diabetic complications. Chronic hyperglycemia also seems to be a significant and independent, albeit weaker risk factor for macrovascular disease [2]. Other adverse consequences of hyperglycemia include an increased susceptibility to infections [3]. These complications affect tissues wherein glucose utilization is predominantly non-insulin-dependent. In addition,

high concentrations or flux rates of glucose can exert adverse metabolic consequences on insulin-dependent tissues that regulate glucose disposal. High concentrations of glucose can by themselves cause two of the principal hallmarks of type 2 diabetes, namely deficiencies of insulin secretion and insulin action, both in animals [4,5] and in humans [6].

The term "glucose toxicity" was first applied to these phenomena by Rossetti and DeFronzo in 1990 [7], although the term had been used earlier to describe other adverse effects of hyperglycemia. In this review, we will restrict the use of the term to the ability of excess glucose to alter normal glucose homeostasis itself, and further restrict the discussion to those effects that are mediated by metabolism of glucose through its normal pathways. Thus, we will exclude effects of hyperglycemia that are, for example, mediated by nonenzymatic glycation or hyperosmolarity, even though these are of unquestioned importance in diabetes. We also acknowledge that the use of the term "toxicity" may not be the most appropriate for at least two reasons: Firstly and most obviously, glucose does not fit most definitions of "toxin," and secondly, some of the "toxic" manifestations of glucose such as insulin resistance can also be seen as adaptive mechanisms that actually protect the organism from other, potentially even worse consequences of high nutrient fluxes. We also emphasize that glucose toxicity is but one of many pathogenetic mechanisms operative in type 2 diabetes. There are other routes to insulin resistance and β-cell failure such as inflammation, lipotoxicity, and others that operate in concert with glucose toxicity to create and maintain the full diabetic phenotype.

In this review, after a brief summary of the pathophysiology of hyperglycemia, we will review the evidence that hyperglycemia can cause insulin resistance and impaired insulin secretion. We will then consider the underlying molecular mechanisms for, and finally the clinical relevance of, glucose toxicity.

Hyperglycemia and glucose utilization

The mass-action effect of glucose

In virtually all tissues except the brain, glucose, at a fixed insulin concentration, promotes its own utilization in a concentration-dependent manner (Figure 27.1) [8]. In insulin-sensitive tissues, the glucose-induced increase in glucose utilization is dependent upon the insulin concentration. For example, an increase in the blood glucose concentration from a fasting concentration from 5 to a peak postprandial concentration of $8.9\,\mathrm{mmol\,L^{-1}}$ (from 90 to $160\,\mathrm{mg\,dL^{-1}}$) increases the rate of whole-body glucose utilization two- to threefold more in the presence of postprandial (serum insulin $50-160\,\mathrm{mU\,L^{-1}}$) than fasting (insulin $10-20\,\mathrm{mU\,L^{-1}}$) serum insulin concentrations [8]. This mass-action effect of glucose is quite significant if one compares it to the rate of whole-body glucose utilization which averages $\sim2\,\mathrm{mg\,kg^{-1}\,min^{-1}}$ after an overnight fast, and increases two- to threefold to $\sim5-7\,\mathrm{mg\,kg^{-1}\,min^{-1}}$ after a meal [9]. As discussed later, the mass-action effect of glucose has important implications for the understanding of the mechanisms underlying glucose toxicity.

Consequences of the acute stimulatory effect of hyperglycemia on postprandial glucose disposal in patients with type 1 and 2 diabetes

Whole-body glucose uptake can be accurately quantitated, using the insulin clamp technique during maintenance of similar glucose and insulin concentrations in normal subjects and diabetic patients [10]. Under such conditions, insulin resistance is observed, that is, the rate of glucose uptake is, on average, reduced in both patients with type 1 and 2 diabetes [11]. If, however, the rate of glucose uptake is measured in patients
Figure 27.1 The mass-action effect of glucose. These dose-response curves were created in humans by inhibiting endogenous insulin secretion with somatostatin in healthy volunteers and by then increasing glucose and insulin concentrations to desired levels on separate days. Doubling the plasma glucose concentration from 5 to $10\,\mathrm{mmol\,L^{-1}}$ significantly increases the rate of glucose uptake. The mass-action effect of glucose is dependent upon the ambient insulin concentration and is much greater at postprandial than fasting insulin concentrations. Source: Adapted from Yki-Järvinen et al. 1987 [8].

with type 1 [12] or 2 [9] diabetes under conditions simulating the actual postprandial glucose and insulin concentrations found in these patients, the rate of absolute insulin-stimulated glucose uptake is normal. This is explained by the ability of hyperglycemia, via glucose mass-action, to compensate for the reduction in glucose utilization caused by insulin resistance. In the absence of any insulin resistance, the mass-action effect of glucose would lead to overutilization of glucose not only in non-insulin-dependent but also insulin-dependent tissues. In non-insulin-dependent tissues not protected by the blood–brain barrier such as peripheral nerves, the kidney, and retina, the rate of glucose utilization is chronically elevated under hyperglycemic conditions, and is a key pathophysiologic abnormality leading to diabetic microvascular complications [1,2]. In contrast, the normal glucose flux to insulin-sensitive tissues, such as skeletal muscle, spares them from hyperglycemia-induced damage.

Chronic hyperglycemia as a cause of insulin resistance

Insulin resistance in patients with type 1 diabetes—a consequence of glucose toxicity?

Insulin resistance both precedes and predicts type 2 diabetes and therefore is not merely due to hyperglycemia [13]. In the case of type 1 diabetes, it is clear that insulin resistance is an acquired and reversible phenomenon since insulin sensitivity is completely normalized during remission of the disease [14]. In these patients, insulin resistance of glucose utilization is predominantly localized to skeletal muscle [15]. Since the peripheral (although not the portal) insulin concentration is usually similar to that in normal subjects in insulin-treated patients [16], insulin deficiency cannot explain insulin resistance in skeletal muscle.

Induction of *in vivo* insulin resistance by hyperglycemia

In type 1 diabetic patients lacking endogenous insulin secretion, effects of hyperglycemia per se on insulin action can be examined. In such a study, insulin-stimulated glucose uptake was measured on two occasions, after 24 hours of hyperglycemia induced by an intravenous glucose infusion (mean diurnal blood glucose $16\,\mathrm{mmol\,L^{-1}}$) and after 24 hours of normoglycemia ($6\,\mathrm{mmol\,L^{-1}}$), in the face of maintaining identical diurnal serum insulin profiles by continuous subcutaneous insulin infusion [6,15] (Figure 27.2). After 24 hours of hyperglycemia, the rate of whole-body glucose uptake was consistently lower than after normoglycemia, demonstrating that short-term hyperglycemia can cause insulin resistance in humans [6,15] (Figure 27.2). These observations were subsequently confirmed [17–19].

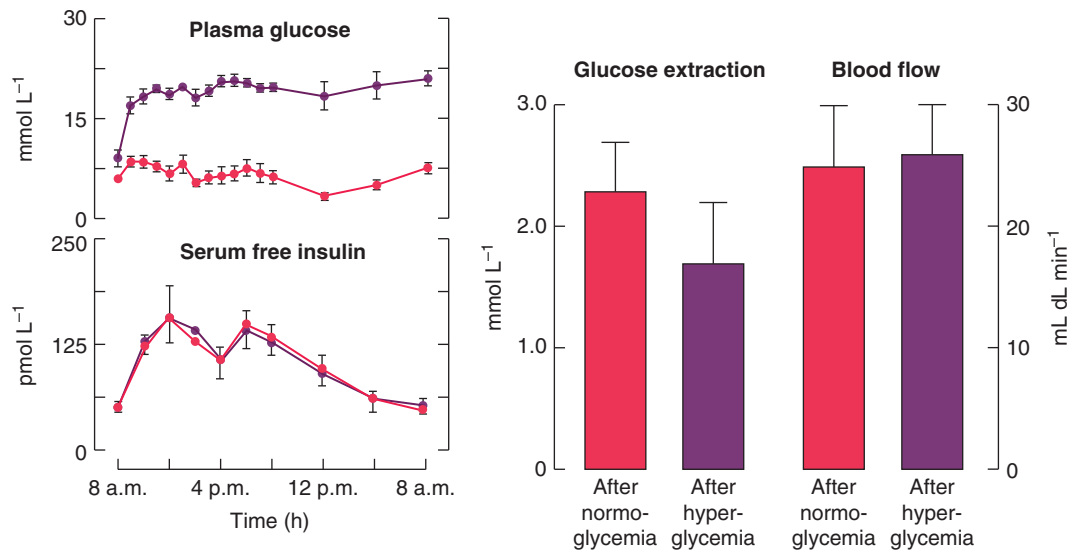
Despite the strong suggestion that glucose per se was inducing insulin resistance in patients with type 1 diabetes, the complexity of metabolic regulation still left open the possibility that the


Figure 27.2 Induction of insulin resistance by hyperglycemia in C-peptide negative patients with type 1 diabetes. Plasma glucose and serum free insulin concentrations during a normoglycemic day (○), and during a hyperglycemic day (●) induced by infusion of glucose. On both study days, the subjects received identical diets and insulin doses. After each study day, the rate of glucose uptake across the forearm was measured under standardized conditions of glycemia and insulinemia to quantitate insulin sensitivity. Preceding hyperglycemia significantly decreased glucose extraction but had no effect on blood flow. Source: Vuorinen-Markkola et al. 1992 [15].

insulin resistance might result from as yet unidentified factors. Animal models, however, gave clearer proof of the primacy of glucose in this phenomenon. In the rat, for example, removal of 90% of the pancreas causes insulin deficiency, hyperglycemia, and a 30% reduction in insulin-stimulated glucose utilization in skeletal muscle [5]. Selective correction of hyperglycemia with phlorizin, which induces glucosuria via inhibition of glucose reabsorption in the proximal tubule, normalizes glycemia without changing serum insulin concentrations (Figure 27.3). These studies together with the human data provided the first evidence of the ability of the blood glucose concentration itself to regulate insulin sensitivity, and the phenomenon began to be referred to as "*glucose toxicity*" [7,20].

Hyperglycemia as a mediator of insulin resistance in type 2 diabetes

In type 2 diabetes, a large number of studies are consistent with the glucose toxicity concept although interpretation of these studies is sometimes not as simple as the studies of type 1 diabetes because of the complex pathophysiology of type 2 diabetes. For example, it is known that hyperinsulinemia can cause insulin resistance [21,22], and type 2 diabetic patients early in the course of the disease are often hyperinsulinemic. It could be argued, therefore, that any treatment that makes a subject more insulin sensitive will ultimately lower insulin levels, making them more insulin sensitive through that mechanism alone. Likewise, weight loss improves both glycemia and insulin resistance [23] but it is difficult to attribute the causality for the improved insulin sensitivity to glycemia alone in such studies. Nevertheless, the data available are at
Figure 27.3 The rate of whole body glucose disposal measured under similar euglycemic hyperinsulinemic conditions in control rats (CON), 90% pancreatectomized rats (PANX), and in phlorizin-treated diabetic rats (PHLOR). Normalization of plasma glucose concentrations with phlorizin did not change insulin concentrations but was still able to reverse insulin resistance in the PANX rats. Source: Adapted from Rossetti et al. 1987 [5].

least consistent with the concept of glucose toxicity. Garvey and coworkers, for example, demonstrated that 3 weeks of intensive insulin therapy significantly improved the maximum glucose disposal rate, endogenous glucose output, and insulin secretory capacity [24], and similar findings were also obtained in other laboratories [25]. The fact that basal insulin levels were unchanged in the weight loss study [23] and increased after intensive insulin therapy [24] suggest that insulinemia per se was not the driving force for the changes in insulin sensitivity. Furthermore, other therapeutic interventions such as sulfonylureas also improve insulin sensitivity, consistent with

the concept that glucose was a principal driver of the insulin resistance prior to therapy.

Since that time, additional support for this concept has been obtained from a wide variety of *in vitro* and *in vivo* models, a few examples of which follow. The *in vitro* studies are particularly compelling because of the ability to isolate glucose as a dependent variable. Insulin-stimulated glucose transport in muscle strips of hyperglycemic type 2 diabetic patients was lower than that of normoglycemic subjects but prolonged exposure to normoglycemia completely reversed that defect [26]. Isolated adipocytes also respond to high concentrations of glucose by desensitizing their glucose transport system [27]. Numerous other seminal studies in animals that support the concept of glucose toxicity as a major determinant of insulin sensitivity have been reviewed in the past and will not all be recapitulated here [7,20].

Physiologic basis of glucose-induced insulin resistance *in vivo*

In insulin-treated patients with type 1 diabetes, in whom glucose toxicity appears to be the major cause of insulin resistance, direct quantitation of tissue glucose uptake during insulin stimulation using positron emission tomography has demonstrated that skeletal muscle is the predominant tissue responsible for the defect in insulin-stimulated glucose utilization [28]. Since a substantial fraction of whole-body glucose oxidation is independent of insulin, rates of whole-body glucose oxidation have to be corrected for the estimated contribution of this component of glucose oxidation [29]. When this is done in patients with type 1 [12] or type 2 [30] diabetes, the fractions of glucose oxidized and disposed of nonoxidatively (the sum of glycogen synthesis and nonoxidative glycolysis) are similar to those in normal subjects. These data suggest that regardless of the primary cellular process causing insulin resistance, the ultimate gate-keeper for cellular glucose uptake is located at the level of glucose transport or phosphorylation. In support of this, muscle glucose-6-phosphate concentrations are similar in insulin-resistant patients with type 1 diabetes under conditions where glucose flux is acutely normalized by hyperglycemia under hyperinsulinemic conditions as under conditions of normoglycemic hyperinsulinemia [12]. Since both GLUT4-mediated glucose transport [31] and glucose phosphorylation by hexokinase II [32] are regulated by insulin, either transport or phosphorylation could be rate-limiting for glucose disposal. Another hypothetical possibility is that glucose delivery could be rate-limiting for glucose disposal. Insulin, at physiologic concentrations, increases blood flow, depending on factors such as limb muscularity and physical fitness from −10 to 80% (mean in 75 studies around 20%) [33]. During a similar time period and at similar insulin concentrations, glucose extraction, as determined from the AV-glucose difference across a limb, increased 1000 to 2000% within 30–60 minutes. Although defects in blood flow may be observed at supraphysiologic insulin concentrations in patients with type 1

or type 2 diabetes, studies performed at physiologic insulin concentrations locate impaired insulin action exclusively to glucose extraction [33]. Taken together these data localize hyperglycemia-induced insulin resistance of glucose utilization to early steps in glucose uptake in skeletal muscle. This defect is accompanied by similar relative reductions in glucose oxidation and storage.

Chronic hyperglycemia as a cause of impaired insulin secretion

In 1948, Lukens and Dohan administered large doses of glucose to normal cats and induced permanent hyperglycemia, hydropic degeneration of the islet of Langerhans, and ketonuria in 4 out of 35 cats studied [34]. These investigators proposed that hyperglycemia could play a role in the pathogenesis of diabetes. In recent years, several approaches have been used to directly examine the harmful effects of chronic hyperglycemia on insulin secretion. These studies have established that chronic hyperglycemia impairs β-cell responsiveness to glucose although the exact biochemical mechanism(s) mediating this effect remain to be clearly defined.

Insulin secretion during experimental hyperglycemia

In normal subjects, β-cell hyperresponsiveness and α-cell hyporesponsiveness is observed after mild hyperglycemia induced by glucose infusions [35]. However, exposure to higher glucose concentrations ($12.6 \, \text{mmol} \, L^{-1}$) for 68 hours has been reported to be associated with significant reduction in insulin secretion in humans [19]. As discussed under section "Clinical significance" later, treatment studies in patients with type 2 diabetes have provided additional support for the idea that chronic hyperglycemia impairs insulin secretion also in humans.

Since the early experiments in cats [34], the ability of chronic hyperglycemia to desensitize the β cell to glucose has been convincingly documented in animal models. In the partially pancreatectomized dog, maintenance of plasma glucose at greater or equal to $14 \, \text{mmol} \, L^{-1}$ for two weeks induces persistent hyperglycemia, loss of glucose induced insulin secretion, ketonuria, and weight loss [36]. Morphometric analysis of the endocrine pancreas revealed a profound reduction in the number and size of islets. These changes were not observed in portions of pancreases removed prior to the glucose infusions or in pancreases of similarly pancreatectomized dogs not subjected to hyperglycemia. Leahy and Weir infused normal rats *in vivo* with various concentrations of glucose and measured the insulin response thereafter *in vitro* using the isolated perfused pancreas [37]. Rats infused with 35% glucose showed a severely blunted insulin response to glucose after 48 hours, and in rats infused with 50% glucose for 48 hours, the glucose-induced insulin response was totally lost. Addition of phlorizin to the 50% glucose infusion after 48 hours for an additional 48-hour
Figure 27.4 Effects of selective normalization of glucose concentrations, without changing insulin concentrations, on insulin responses to arginine (0 to 30 min) and glucose (80–140 min). The insulin response to arginine was exaggerated in diabetic animals while both first- (80–90 min) and second- (90–140 min) phase responses to glucose were blunted before treatment in the diabetic (90% pancreatectomized) animals. Phlorizin treatment restored both responses to arginine and glucose to normal. Source: Adapted from Rossetti et al. 1987 [4].

period completely restored the insulin response [37]. Similar results were obtained by Rossetti et al. who treated mildly hyperglycemic rats with a continuous infusion of phlorizin for 4 weeks [4]. The insulin responses to arginine, glucose, and arginine plus glucose were determined *in vitro* using the hyperglycemic clamp technique. Normalization of glycemia by phlorizin normalized all aspects of abnormal insulin secretion, that is, the subnormal first and second phase insulin responses to glucose, the increased insulin response to arginine, and the potentiation of insulin secretion by hyperglycemia during infusion of arginine [4] (Figure 27.4). Correction of hyperglycemia with phlorizin has also been shown to restore glucose-induced suppression of glucagon release in insulin-deficient alloxan diabetic dogs [38].

Molecular mechanisms of glucose toxicity

Carbons from ingested glucose are incorporated into nearly every class of biologic metabolite and macromolecule, and the metabolism of those molecules generates energy, oxidant byproducts, and inflammatory stress, all of which could contribute to glucose-induced insulin resistance. The complexity of the pathways of insulin signal transduction and its interactions with numerous other regulatory networks suggests that glucose toxicity is unlikely to operate through a single mechanism, and the data are consistent with that presumption. Two leading candidates for the molecular mediators of glucose toxicity are the hexosamine/O-linked glycosylation pathway and redox signaling pathways, and both of these are supported by extensive experimental data that will be summarized in this section. These are unlikely to be the only mechanisms for glucose toxicity,

however. Excess glucose is metabolized to lipid, for example, and there is no question that excess lipid fluxes through mechanisms involving activation of protein kinase C, ceramide synthesis, accumulation of incompletely metabolized intermediates, and others can contribute to insulin resistance and β-cell failure in diabetes. For consideration of these pathways and mechanisms of vascular complications of diabetes the reader is referred to the other chapters in this volume and several excellent recent reviews [39,40]. We will concentrate this review on the more direct products of glucose metabolism that contribute specifically to the metabolic abnormalities of diabetes.

The hexosamine/O-linked N-acetyl glucosamine pathway
The hexosamine biosynthetic pathway and insulin resistance

One metabolic fate of glucose is the hexosamine biosynthetic pathway (HBP), and high flux through this pathway, such as occurs in diabetes or overnutrition, has been convincingly linked to insulin resistance and β-cell failure. In this pathway a relatively small fraction of cellular glucose flux—a few percent in most tissues—is converted to UDP-N-acetylglucosamine (UDP-GlcNAc) and other amino sugars (Figure 27.5). The rate-limiting step is catalyzed by the enzyme glutamine: fructose-6-phosphate amidotransferase (GFA) that catalyzes the synthesis of glucosamine-6-P from fructose-6-P and glutamine. The product of the HBP, UDP-GlcNAc is well placed to serve a nutrient-sensing function, as its production has been shown to be responsive not only to cellular glucose flux [27] but also to the levels and availability of nucleotides [41], fatty acids [41], and amino acids [27]. It is a high-energy intermediate and is therefore also reflective of cellular energy status.

The first evidence of the involvement of the HBP in metabolic regulation was its mediation of glucose toxicity in models of insulin resistance. High concentrations of glucose downregulate insulin-stimulated glucose uptake, and Marshall made a breakthrough in understanding this phenomenon when he demonstrated in adipocytes that glucose metabolism to glucosamine-6-P was required for this effect [27]. Since then, numerous studies have shown that increased hexosamine flux can induce insulin resistance in cultured cells and whole animals (reviewed in [42]). Many of these studies employed infusion of glucosamine that enters the HBP directly after uptake by glucose transporters and phosphorylation by hexokinase. Interpretations of these studies were criticized because pharmacologic concentrations of glucosamine can compete for glucose uptake, deplete cellular ATP, and even trigger apoptosis [43]. Furthermore, short-term infusion studies may not reflect the full range of posttranslational and transcriptional changes that can result from chronic activation of the HBP. More definitive evidence for the involvement of the HBP in insulin resistance was obtained using animal models wherein chronic but physiologic changes in hexosamine flux were induced by overexpression of GFA in a tissue-specific manner. The results of these studies showed that

the HBP serves a nutrient-sensing function in multiple tissues and affects metabolism in a wide-ranging manner. Specifically:

- overexpression in muscle plus fat, or fat alone results in insulin resistance, downregulation of glucose transport [44–46], and;
- overexpression in β cells results in hyperinsulinemia [47].

These phenotypes mimicked and therefore validated those that had been seen in the infusion models and with glucosamine treatment of explanted tissues [48–50]. Importantly, the effects of increased HBP flux are nonadditive with hyperglycemia [51] and high-fat feeding [52], in inducing insulin resistance suggesting that both hyperglycemia and overnutrition in general may induce insulin resistance through the HBP.

O-linked glycosylation of nuclear and cytosolic proteins as the mechanism for HBP effects on glucose homeostasis

What is the mediator of the effects of the HBP? UDP-GlcNAc is a substrate for enzymatic glycosylation of proteins, suggesting a mechanism for HBP signaling. Since neither N-linked glycosylation nor O-linked glycosylation of secreted proteoglycans are responsive to changes in glucose fluxes, interest in HBP

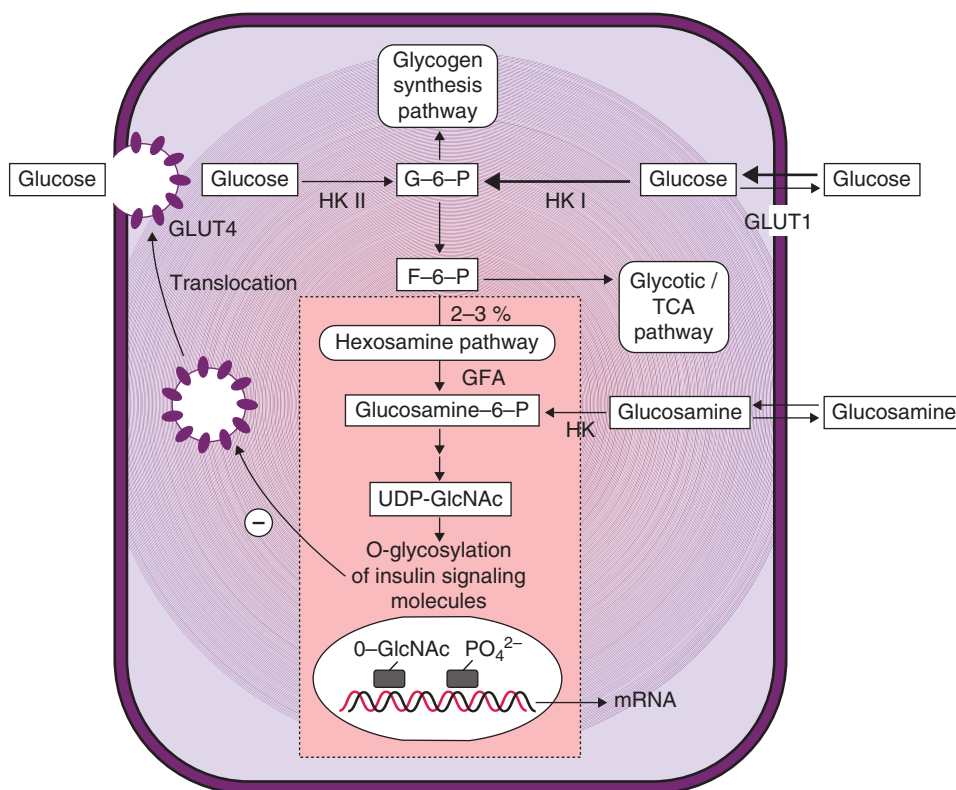
signaling originally focused on the then recently discovered pathway of O-linked glycosylation wherein single O-GlcNAc residues are enzymatically added to serines and threonines of nuclear and cytosolic proteins (Figure 27.5). Discovered by Hart in 1984, this form of glycosylation is dynamic, is commonly found on proteins involved in signal transduction, and is responsive to changes in glucose flux [53,54]. O-glycosylation is often reciprocal with phosphorylation and in some cases occurs on the same residues that are otherwise phosphorylated (e.g. c-myc [55]), further suggesting a potential role in signaling. Glycosylation is accomplished by a single O-linked GlcNAc transferase (OGT) [56] and deglycosylation is by a single known O-GlcNAcase [57]. The enzymologic and biochemical aspects of the pathway involved in protein O-GlcNAc modification have been reviewed recently and will not be described here in further detail [58]. Importantly and consistent with playing a role in glucose homeostasis, the pathway is highly feedback-regulated by substrates and transcriptional control of OGT and O-GlcNAcase such that in cultured cell lines the minimum levels of glycosylation of at least some proteins


Figure 27.5 The hexosamine metabolic pathway discovered by Marshall et al. [27]. A small fraction (2–3%) of glucose, which enters insulin-sensitive tissues either using the insulin-independent glucose transporter GLUT1 and glucose phosphorylating enzyme hexokinase I (HKI), or with the help of the insulin-sensitive glucose transporter GLUT4 and hexokinase II (HKII) is metabolized to hexosamine products in the presence of glutamine. GFA is the rate-limiting enzyme of the pathway. The end-product of the pathway is UDP-GlcNAc, which can be covalently linked to serine and threonine residues on specific proteins (O-glycosylation) such as insulin signaling molecules and GLUT4. O-glycosylation seems to decrease insulin action and GLUT4 translocation resulting in insulin resistance. Initial activation of the pathway is thought to occur via glucose mass action, which is at low insulin concentrations after an overnight fast, and is increased under hyperglycemic conditions. Glucosamine can bypass the rate-limiting step of the pathway and can therefore be used as a tool to study consequences of activation of the hexosamine pathway. G-6-P, glucose-6-phosphate; F-6-P, fructose-6-phosphate; TCA, tricarboxylic acid.

happens to occur at the level of normoglycemia in mammals, 5 mM glucose [59]. Consistent with that finding, the pathway regulates insulin signaling even in the normoglycemic range, demonstrating that it is a physiologic and not solely pathophysiologic ("toxic") regulator [60]. Finally, the pathway's highly evolutionarily conserved role in nutrient homeostasis and hormone responsiveness in *C. elegans* [47,61], *Drosophila* [62], and plants [63] speaks to its importance in metabolic regulation.

The first direct evidence that the O-glycosylation mediated the observed effects of the HBP on insulin resistance was demonstrated by overexpression of the enzyme responsible for this glycosylation, O-linked GlcNAc transferase (OGT), in skeletal muscle and fat under control of the GLUT4 promoter [64]. This maneuver recapitulated the insulin resistance and hyperleptinemia seen with overexpression of GFA in the same tissues [44]. Other early evidence for the role of OGT came from demonstrations in Hart's laboratory that enzymatic inhibition of the enzyme O-GlcNAcase in 3T3L1 cells leads to insulin resistance in parallel with increased O-linked glycosylation of proteins [65]. It should also be pointed out, however, that there are models of insulin resistance that do not involve increased levels of O-GlcNAc [66], and conversely, there are circumstances in which increased O-GlcNAc may not lead to insulin resistance [67]. In both of the latter cases, extremely high and unphysiologic levels of protein O-GlcNAc modification were achieved pharmacologically.

Modification of metabolic enzymes and transcription factors by O-GlcNAc has been shown to alter their function in a way that is consistent with the phenotypes observed in animals. Glycogen synthase (GS), the first protein shown to be affected by phosphorylation, is also a target of the HBP/O-GlcNAc pathway [68]. Exposure of cultured adipocytes to high glucose or glucosamine, or streptozotocin-induced diabetes in mice renders the enzyme insulin resistant and less sensitive to its principal positive allosteric regulator, glucose-6-phosphate [69], and this is related not to changes in phosphorylation but rather to levels of O-glycosylation. O-glycosylation of GS therefore mimics phosphorylation and inhibits the enzyme, but in a way that cannot be reversed by insulin action. Thus, O-GlcNAc acts as a dominant negative signal that renders GS insulin resistant and limits glycogen accumulation in situations of chronic hyperinsulinemia and nutrient excess.

Many other components of the insulin signal transduction pathway are modified by O-GlcNAc, most often in an inhibitory fashion. Rats infused with glucosamine, for example, exhibit insulin resistance of skeletal muscle through decreased phosphorylation of insulin receptor substrate-1 (IRS-1) and its association with phosphatidylinositol 3-kinase (PI3K) [56]. IRS-1 [65], the downstream insulin signaling kinase Akt [70], proteins of glucose transporter vesicles [71], the crucial transcriptional metabolic regulator FOXO1 [72], and the nutrient sensor AMP-activated protein kinase (AMPK) [73] are also modified by O-GlcNAc, with proven functional consequences. A recent and particularly exciting insight into the crosstalk between hormone signaling and O-GlcNAc is that OGT contains a domain that recognizes phosphatidylinositol 3,4,5-trisphosphate [74]. This results in the recruitment of OGT to the plasma membrane after activation of PI3K through the insulin/IR/IRS-1 pathway. Thus, even as the insulin signal transduction pathway is being activated, steps are also being taken by the cell to attenuate that acute signal through increased O-glycosylation of many of the same proteins.

These effects of O-GlcNAc on insulin signaling, particularly in rodent models wherein the levels can be effectively and chronically modulated in the physiologic range, are very consistent with the insulin resistance associated with "glucose toxicity" seen in humans. The direct evidence that the HBP may be directly involved in human diabetes, however, is limited and as yet inconclusive, largely because of experimental limitations. In humans, glucose and insulin infusions increase levels of O-GlcNAc in skeletal muscle [75]. Human studies, however, have revealed modest [76] or no [77] effects of glucosamine infusion on insulin resistance. These studies are insufficient to refute the hexosamine hypothesis, however. The glucosamine infusions may not have reached threshold concentrations for sufficient lengths of time or may not have targeted key tissues such as liver or adipose tissue. For example, in the negative study cited earlier, glucosamine infusion into the forearm did not lead to insulin resistance [78] but the study was limited in its sensitivity to detect a modest effect, and moreover the principal target for producing insulin resistance in muscle may be the adipocyte rather than muscle itself [45]. Other evidence in humans does support a role for the HBP. We showed, for example, that insulin resistance in type 2 diabetes was correlated with GFA levels in skeletal muscle [30,54]. Leptin mRNA and protein levels are also correlated with adipocyte UDP-GlcNAc levels that are in turn well correlated with body mass index in humans [79].

O-GlcNAc signaling as an adaptive response to overnutrition

The effects are consistent with a role for O-GlcNAc in damping acute hormone- and phosphorylation-mediated signals in situations of chronic nutrient excess. Although discovered in the context of diabetes, the afore-mentioned changes mediated by the HBP can also be viewed as adaptive responses to excess nutrient flux: muscle cells protect themselves from excess glucose fluxes and the excess nutrients are eventually stored as fat. Indeed, if insulin signaling were not dampened and glycogen synthesis were effectively engaged even with overeating, a pound of ingested carbohydrate would result in approximately four pounds of hydrated glycogen in muscle, and it is easy to visualize diets rich in sodas and donuts resulting in the development of glycogen storage diseases. With age and chronic overstimulation of the pathway, however, animals with chronically increased hexosamine flux exhibit several of the maladaptive features of the type 2 diabetes syndrome including obesity, hyperlipidemia, insulin resistance, and β-cell failure

[44,47,80]. Thus, the HBP can be viewed as both physiologic and pathophysiologic, triggering normal nutrient regulation as well as aspects of "glucose toxicity" and the metabolic syndrome.

O-GlcNAc and other aspects of glucose toxicity

The O-GlcNAc pathway also plays a role in hepatic glucose production and insulin secretion, the other key abnormalities of type 2 diabetes. The glycosylation of FOXO1, a key regulator of gluconeogenesis, was mentioned earlier. This glycosylation is mediated, at least in part, through the binding of OGT to O-GlcNAc-modified PGC1α, resulting in the targeting of OGT to binding partners of PGC1α that include the FOXOs [59]. It was also demonstrated that overexpression of O-GlcNAcase in the liver of insulin resistant *db/db* mice significantly improved glucose and insulin tolerance [81]. This was mediated by decreased O-glycosylation of the cyclic adenosine monophosphate response element-binding protein 2 (CRTC2) which led to decreased expression of gluconeogenic enzymes.

Transcriptional regulation by O-GlcNAc has been shown to play a major role in the pancreatic β cell, where OGT is highly expressed [82]. GFA overexpression targeted to the β cell resulted in early hyperinsulinemia but eventual β-cell failure as the transgenic mice age [47]. Conversely, O-GlcNAcase overexpression led to early insulin deficiency but long-term protection from age- and obesity-related β-cell failure [83]. In β cells, the best established mechanisms for the effects of O-GlcNAc signaling are transcriptional. Transcription of the insulin gene is regulated by the binding of several transcription factors including Pdx-1, NeuroD1, and MafA, all three of which are directly or indirectly regulated by O-GlcNAc (reviewed in [84]). In these examples, O-GlcNAc serves a function that stimulates insulin secretion, which would be predicted to be antidiabetic and "antiglucotoxic," but as pointed out when these acute effects are translated into chronic models, they become prodiabetic through unclear mechanisms [47]. Insulin-independent downstream effects of O-GlcNAc, for example on inflammatory [85] or angiogenic [86] pathways, may also be at play.

Oxidative stress from excess glucose metabolism

Another major fate of glucose that has been linked to glucose toxicity is the oxidative stress that results from oxidation of abnormally heavy glucose loads. As was the case for the term "glucose toxicity," the use of the words "oxidative stress" may connote a purely deleterious effect such as the accumulation of oxidized and dysfunctional lipids, proteins, and nucleic acids because of excess free radicals and other oxidants (e.g. peroxide, peroxynitrite, and nitric oxide), and that is certainly part of the mechanism. It is also clear, however, that the cellular redox state is equally important to the physiologic regulation of metabolism through multiple mechanisms including altering the ratios of reduced to oxidized glutathione, redox status of thiols in proteins such as thioredoxin, activity of key phosphatases, other redox-dependent posttranslational modifications such as

protein nitrosylation, levels and activities of adipokines, and others. The reader is directed to recent reviews in this area for further details (e.g. [87–89]). Although the most obvious source for these reactive species is oxidative phosphorylation, other sources that are particularly relevant to diabetes and glucose toxicity include reactive products of advanced glycation end-products and glyceraldehyde autoxidation (reviewed in [90]).

Oxidative stress and β-cell failure in diabetes

Increasing evidence links oxidative stress provoked by hyperglycemia to β-cell damage [91,92]. Interestingly, the latter reference links hexosamine signaling to induction of oxidative stress, providing one potential link between these important processes in glucose toxicity. β-Cells are particularly susceptible to oxidative stress because they contain intrinsically low concentrations of antioxidant enzymes [93]. In addition, β cells are programmed to target most of their glucose to oxidative phosphorylation for signaling of insulin secretion, so that in states of hyperglycemia there will be an added stress of increased production of oxidant species on top of the decreased ability to reduce those species. Additivity of oxidant stress with high concentrations of glucose has been directly demonstrated [94]. These findings have led to multiple studies that demonstrate that transgenic overexpression of antioxidant enzymes (both cytosolic and mitochondrial superoxide dismutase, catalase, and glutathione peroxidase) all protect from β-cell failure in isolated islets, cultured insulin-producing cells, and rodent models [95,96]. As would be predicted from these data, insulin secretory defects and the changes in genes controlling insulin secretion in several experimental models of glucose toxicity have also been prevented by various antioxidant treatments such as N-acetylcysteine, troglitazone, and aminoguanidine [91,97].

Cellular mechanisms for effects of hyperglycemia on insulin secretion

Exposure of the β cell to experimental chronic hyperglycemia induces specific desensitization to glucose whereas the insulin response to other secretagogues such as arginine [37], leucinenobreak [98], and isoproterenol [99] are either preserved or exaggerated. In keeping with this, the insulin content of the islet is not reduced by hyperglycemia to an extent that would account for the degree of glucose-induced desensitization [37]. Such selective desensitization to glucose but not other secretagogues such as arginine is also seen during the early types 1 and 2 diabetes. This desensitization is considered entirely reversible by restoration of normal glucose concentrations [100]. Consistent with these observations, one mechanism by which antioxidants restore normal insulin secretion is direct preservation of mitochondrial function and stimulus-secretion coupling [101]. Insulin content also is diminished by hyperglycemia: in animals and cell lines, hyperglycemia induces a gradual loss of insulin gene expression and gene and protein expression levels of pancreas duodenum homeobox-1 (PDX-1) and MafA

transcription factors, critical regulators of the insulin gene, and these effects are also reversed with antioxidant treatment [91].

Oxidative stress and insulin resistance

The association of oxidant stress with insulin resistance has been documented in humans for almost two decades [102]. These effects are mirrored in cell culture models, wherein it has also been shown that antioxidants such as α-lipoic acid protects against the effects of oxidant stress on insulin signaling pathways in cultured adipocytes and myocytes [103]. These studies have prompted trials of antioxidants in humans, wherein short-term improvements in insulin sensitivity are seen [104], although the long-term benefits of antioxidant therapies in type 2 diabetes have been less encouraging. Part of the reason for the latter is likely due to the complexity of oxidant stress on insulin signaling and the function of insulin-responsive tissues. Oxidant stress in diabetes is not only linked to excess glucose and lipid fluxes, but also to ancillary factors such as tissue iron levels [105]. The targets of oxidant stress include mitochondrial respiration rates [106], the proximal insulin-signaling pathway and downstream associated pathways such as p38/MAP kinase and Jnk which are linked to inflammatory signaling [90,107], the AMP-activated protein kinase pathway [108], and numerous others, not to mention more nonspecific effects caused by the nonspecific oxidative damage to DNA, lipids, and proteins. Hence, delivery of the right species of antioxidant to the right tissues at sufficiently sustained levels will be a daunting task.

Clinical significance of glucose toxicity

Type 1 diabetes

After diagnosis of type 1 diabetes, initiation of insulin therapy induces partial clinical remission in ∼30% of the patients during the first year [96]. This honeymoon period is characterized by normoglycemia, recovery of endogenous insulin secretion, and by improved insulin sensitivity [109]. Although correction of several alterations secondary to insulin deficiency, such as increased counterregulatory hormone secretion [110], hyperosmolarity [111], acidosis [112], electrolyte changes [113] and high free fatty acids [114] could contribute to normalization of insulin secretion and sensitivity, reversal of glucose toxicity may also be of importance for the occurrence of remission. In the DCCT, 855 patients had had type 1 diabetes for 1 to 5 years at baseline and of these 303 were considered C-peptide responders (C-peptide level, 0.20 to 0.50 pmol mL^{-1} after ingestion of a standardized, mixed meal). Responders receiving intensive therapy maintained a higher stimulated C-peptide level and a lower likelihood of becoming nonresponders than did responders receiving conventional therapy (relative risk reduction, 57%) [1].

As discussed earlier, in type 1 patients with long-standing disease, chronic hyperglycemia can be regarded as the key factor responsible for insulin resistance. Therefore and in contrast to the results obtained in patients with type 2 diabetes (see later), insulin sensitivity can be markedly improved and even normalized in type 1 patients by optimizing insulin therapy [20]. The enhanced insulin sensitivity explains why glycemic control can be improved without necessarily having to increase the daily dose [115,116]. Thus, although the loss of insulin secretion is irreversible in type 1 diabetes, insulin sensitivity is amenable to marked modification by alterations in glycemic control.

Type 2 diabetes

Data from both several cross-sectional and prospective studies have documented that hyperinsulinemia and insulin resistance both precede and predict the subsequent development of type 2 diabetes. The etiology of insulin resistance is multifactorial and involves familiar/genetic and acquired components. Consequently, one would not expect normalization of insulin sensitivity by improved glycemic control. In keeping with this, insulin resistance has been a uniform finding in patients with type 2 diabetes and has only been partially reversed by, for example, aggressive insulin therapy [7,24,117–119].

Both weight loss [23,120–123], sulfonylureas [123], and insulin therapy [24,25,123–126] improve insulin secretion. Since neither insulin therapy nor weight loss have any direct stimulatory effects on insulin secretion, their effects could be mediated indirectly via diminution of glucose toxicity on β-cell secretion. Indeed, the "extrapancreatic effect" (improved insulin sensitivity) of sulfonylureas has been entirely attributed to amelioration of insulin resistance via lowering of the plasma glucose concentration [127].

In terms of practical clinical care, the fact that the core defects that contribute to hyperglycemia in type 2 diabetes, including excess hepatic glucose production, impaired insulin secretion, and insulin resistance, all improve with control of glycemia means that control of type 2 diabetes should be easier to maintain after a relatively short period of near-normoglycemia. In the largest of such studies 382 Chinese patients were randomly assigned to therapy with insulin or oral hypoglycemic agents [128]. Treatment was stopped after normoglycemia was maintained for 2 weeks after an initial treatment period of ∼10 days. Patients were then followed for 1 year on diet and exercise alone. Better glycemic control was achieved with insulin therapy than with oral agents and the remission rates were higher at 1 year in those treated initially with insulin as compared to oral hypoglycemic agents. The acute insulin response was significantly improved by intensive glucose control with insulin. This increase was sustained at 1 year in the insulin groups but significantly declined in patients treated with oral hypoglycemic agents [128]. This study as well as many smaller studies (reviewed in [129]) suggest that short-term intensive insulin therapy early in the course of may offer favorable long-term effects on β-cell function.

Monogenic disorders of the β cell

Ali J. Chakera and Andrew T. Hattersley

University of Exeter Medical School, Exeter, UK; Royal Devon and Exeter Hospital Exeter, UK

Key points

- Monogenic β-cell diabetes accounts for 1–2% of diabetes.
- Maturity onset diabetes of the young (MODY) is the commonest form of monogenic β-cell diabetes. MODY can be divided into two clinical groups: mutations in *Glucokinase* (GCK-MODY), and mutations in the transcription factors—HNF1A and HNF4A (TF-MODY).
- People with GCK-MODY have stable fasting hyperglycemia ($5.5–8.0\,\text{mmol L}^{-1}$) present from birth and do not have significant microvascular complications. Treatment is not required (except in pregnancy).
- TF-MODY diabetes develops in childhood/early adult life and deteriorates over time. Patients are very sensitive to sulfonylurea treatment which is recommended as initial treatment although subsequently insulin treatment may be required. Microvascular complications are common and patients with HNF1A-MODY have an increased cardiovascular risk.
- Maternally inherited diabetes and deafness (MIDD) accounts for approximately 0.5% of diabetes. It is caused by a mitochondrial gene mutation (np3243) and is characterized by maternally inherited diabetes that is initially noninsulin requiring, which usually develops after the onset of sensorineural deafness.
- Neonatal diabetes is a monogenic β-cell diabetes which is diagnosed in the first six months of life. Neonatal diabetes can be permanent or transient, the latter of which remits as an infant, but often reoccurs in later life.
- The commonest causes of neonatal diabetes result from mutations in the K_{ATP} mutation and excellent glycemic control can be achieved with high-dose sulfonylurea tablets instead of insulin injections.

Introduction

This chapter will concentrate on the monogenic disorders of the β cell that account for 1–2% of diabetes. They are discrete disorders which are a significant cause of diabetes in their own right. Correct molecular diagnosis is important to predict clinical course, explain other associated clinical features, enable genetic counseling, diagnose family members, and most importantly guide appropriate treatment. In addition to this clinical importance, the discovery and study of monogenic disorders has given further insight into the physiology and pathophysiology of the β cell.

In normal health the pancreatic β cell is a finely tuned system that ensures appropriate insulin release in order to maintain homeostasis of blood glucose within a narrow physiologic range. Problems with the β cell can result in diabetes, or more rarely, oversecretion of insulin and hypoglycemia. The most common disease resulting from β-cell dysfunction in humans is type 2 diabetes (T2DM). This is a complex polygenic disorder that is likely to represent a heterogeneous spread of defects.

Monogenic β-cell disorders in key aspects of β-cell function

To understand the pathophysiology of the β cell in monogenic diabetes it is important to outline the process whereby the β cell senses glucose and translates this into an appropriate release of insulin. Figure 28.1 shows a schematic representation of the β cell and the legend describes the process of glucose-insulin secretion coupling. The sites of monogenic defects (indicated on the figure) that cause diabetes or hypoglycemia are as follows:

- GLUT2: GLUT2 mutations cause Fanconi–Bickel syndrome. The phenotype is predominantly due to defects in hepatic GLUT2 causing glycogen storage disease, rather than pancreatic GLUT2. This will not be discussed in this chapter.
- GCK: Loss of function mutations in *GCK* cause a rise in fasting glucose with maintained homeostasis, referred to as glucokinase—maturity onset diabetes of the young (GCK-MODY).
- Glycolysis: Defects in glycolysis are described in transcription factor MODY (TF-MODY) due to mutations in *Hepatocyte nuclear factor* (*HNF*)-1 *alpha* (*HNF1A*) and *HNF4A*.
Figure 28.1 Glucose enters the β cell via the GLUT2 transporter where it is phosphorylated to glucose-6-phosphate (G6P) by the enzyme glucokinase (GCK). G6P is metabolized via the glycolytic pathway to pyruvate. Pyruvate enters the mitochondria and is metabolized via the citric acid cycle to produce a rise in intracellular ATP and a fall in ADP. This increase in ATP/ADP acts to close ATP-dependent K channels (Kir6.2/SUR1) allowing a rise in the membrane resting potential, which triggers a voltage gated calcium channel to open, allowing calcium influx. It is this calcium influx that is the trigger for insulin exocytosis.

- Mitochondria: Mitochondrial defects are described in: maternally inherited diabetes and deafness (MIDD).
- K_{ATP} channel: Mutations in *SUR1* and *Kir6.2* (components of the K_{ATP} channel) cause both permanent and temporary neonatal diabetes and have been shown to cause hyperinsulinemia of infancy.

- Endoplasmic reticulum: Wolfram syndrome (*WFS-1*) and Wolcott–Rallison syndrome (*EIF2AK3*) genes encode proteins that localize to the endoplasmic reticulum.
- Insulin: Insulin gene mutations causing mutant insulin which misfold and cannot be secreted resulting in neonatal diabetes.

Clinical categories of monogenic β-cell disorders

This chapter will discuss the three most important clinical categories of monogenic disorders of the β cell: (1) Maturity-onset diabetes of the young, (2) Neonatal diabetes, and (3) Diabetes with marked extrapancreatic features (see Figure 28.2).

Maturity-onset diabetes of the young

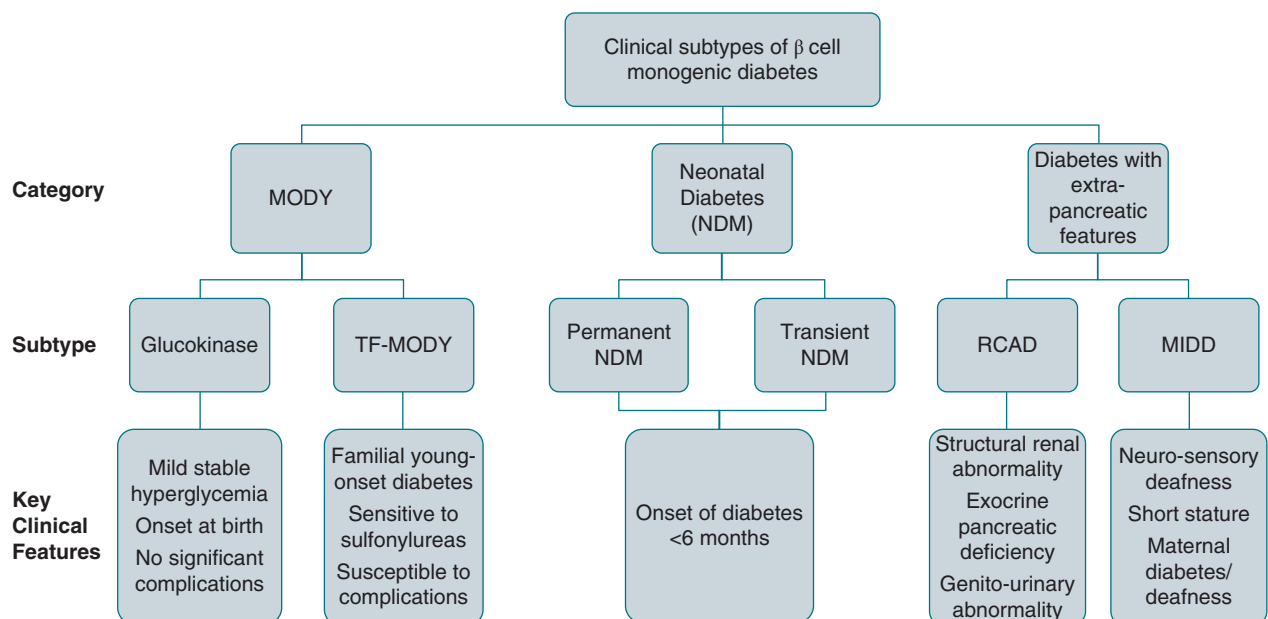
Maturity-onset diabetes of the young (MODY) refers to group of monogenic subtypes of diabetes characterized by young onset (usually before 25 years) of non-insulin-dependent diabetes, β-cell dysfunction that is inherited as an autosomal dominant trait. Mutations in at least 10 genes have been found to cause MODY; (see Figure 28.3) the common subtypes are due to mutations in *GCK*, *Hepatocyte nuclear factor 1-alpha (HNF1A)*, *HNF4A*, and *HNF1B*. The definition of the underlying genes has resulted in the recognition of distinct clinical and physiologic subgroups of MODY with varying clinical course, prognosis, and treatment requirements. Classifications of diabetes by the ADA and the WHO recognize these discrete subtypes.


Figure 28.2 Categorization of the subtypes of monogenic β-cell diabetes. MIDD, mitochondrial diabetes and deafness; MODY, monogenic diabetes in the young; NDM, neonatal diabetes (mellitus); RCAD, renal cysts and diabetes; TF, transcription factor.

Diagnosis of MODY

Table 28.2 shows the key differences between type 1 and type 2 diabetes and MODY in young adults. Over 80% of people with MODY will initially be misdiagnosed with type 1 or type 2 MODY [1]. MODY subjects tend to be (but are not exclusively) non-obese, lack features of the insulin resistance syndrome, and be GAD and IA-2 antibody negative. The strict classic criteria for MODY: (i) age of onset diabetes <25, (ii) non-insulin-dependent diabetes, (iii) family history of diabetes (due to autosomal dominant inheritance), have been successfully applied to genetic studies. However, they have poor sensitivity, missing 50% of patients with a diagnosis of MODY [1]. Recently, an online clinical prediction model has been developed for MODY (a MODY calculator: www.diabetesgenes.org/content/mody-probability-calculator). This allows clinicians to identify those patients that are most likely to benefit from genetic testing based on a pretest probability of MODY, taking into account a patient's age of diagnosis, treatment, BMI, and family history [1]. The importance of a genetic diagnosis of MODY is that these patients often do not need insulin treatment and an appropriate switch of therapy can lead to an improvement in well-being and glucose control.

Prevalence of MODY subtypes

MODY accounts for approximately 1% of non-insulin-dependent diabetes in Europe [1]. Large national collections allow assessment of the relative prevalence of the different subgroups of MODY as shown in Figure 28.3 [2]. The relative prevalence varies, by country, according to how patients are identified. As glucokinase mutations are common ($\cong$0.1% population) but asymptomatic, their frequency will be higher in populations where there is wider screening for and follow-up of abnormal glucose levels in children and young adults.

The MODY phenotypes

The MODY phenotypes can essentially be divided into two distinct clinical groups: glucokinase MODY (GCK-MODY) and transcription factor MODY (TF-MODY). The phenotypes in these two groups are completely different (see Table 28.1),

and it is confusing that they both fall under the same group name of MODY. GCK-MODY is characterized by stable fasting hyperglycemia that is present from birth, nonprogressive, does not require treatment (except in pregnancy), and is not associated with serious vascular complications. TF-MODY diabetes, on the other hand, is not present at birth but usually develops in adolescents/young adults. The two commonest forms are due to mutations in *HNF1A* and *HNF4A*. They are progressive with increasing treatment requirements and are associated with the full range of diabetes-associated microvascular complications [3].

Glucokinase MODY

Glucokinase catalyzes the phosphorylation of glucose to glucose-6-phosphate. Its unique kinetic properties result in the rate of glucose phosphorylation being proportional to the physiologic glucose concentration. This means that the β cell and hepatocyte can respond appropriately to fluctuations in the degree of glycemia. In the pancreatic β cell, glucokinase acts as "the glucose sensor" [4] ensuring insulin release is appropriate to the blood glucose concentration.

Molecular genetics of glucokinase MODY

Coding or intron/exon boundary mutations were first found in the *glucokinase* gene in French and English MODY pedigrees in early 1992 [5,6]. Over 200 different heterozygous loss-of-function mutations have now been described, all causing a similar clinical picture. Expression studies show that the mutations in MODY families may alter the enzyme's affinity or activity for glucose metabolism or phosphorylation or alter structure or stability [7–10]. Homozygous loss-of-function glucokinase mutations are a rare cause of insulin-requiring diabetes presenting in the neonatal period [11]. Gain-of-function mutations cause congenital hyperinsulinism [12].

Phenotype of glucokinase MODY

Subjects with GCK-MODY have fasting hyperglycemia that is present from birth and shows very little deterioration with age [13]. Byrne and colleagues have shown, using graded glucose infusions, that heterozygous mutations in GCK cause a right shift in the insulin response curve leading to a re-setting of the fasting glucose set point [14]. So the majority of GCK-MODY subjects have high fasting plasma glucose within a tight range ($5.5–8 \, \text{mmol L}^{-1}$). There is maintained glucose homeostasis as shown by the small increment in plasma glucose at two hours during an oral glucose tolerance test, albeit at a higher set point than in normal subjects [15]. The HbA1c is raised in people with GCK-MODY with a median value of $50 \, \text{mmol mol}^{-1}$ that, as in normal subjects, deteriorates with age [13]; over half of cases exceed the diagnostic criteria for diabetes. HbA1c values above $64 \, \text{mmol mol}^{-1}$ would suggest an alternative diagnosis and marked worsening of the glycemia suggests that the patient has developed type 1 or type 2 diabetes in addition to their *GCK* mutation. Subjects with GCK-MODY do not get

Table 28.1 Comparison of the clinical characteristics of glucokinase and transcription factor MODY

	Glucokinase MODY	**Transcription factor MODY**
Genetic etiology	Loss-of function mutations in *glucokinase* gene Autosomal dominant	Loss-of function mutations in *HNF1A* and *HNF4A* genes Autosomal dominant
Onset of hyperglycemia	From birth (though asymptomatic)	Second / third decade
Presentation	Usually asymptomatic, detected by screening or on routine testing	Usually symptomatic
Details of hyperglycemia	Mild stable hyperglycemia (fasting glucose 5.5–8 mmol L^{-1}) Minimal increase in glycemia with age (parallel to normals) HbA1c 40–60 mmol L^{-1} (5.7–7.7%)	May be severe (FPG frequently >14 mmol L^{-1} of treatment) Progressive deterioration of glycemia with age HbA1c variable depending on control, may be high (as with type 2 diabetes)
Pattern in an oral glucose tolerance test	Fasting: >5.5 mmol L^{-1} 120 min: increment usually <4.4 mmol L^{-1}	Fasting: often <5.5 mmol L^{-1} 120 min: increment usually >4.4 mmol L^{-1}
Microvascular complications	No significant microvascular complications	Frequent
Macrovascular complications	As normal population	HNF1A: – Raised cardiovascular risk
Pathophysiology	Glucose sensing defect	Insulin secretion maintained at normal glucose values but not increased in hyperglycemia
Extrapancreatic manifestations	None	HNF1A: – Low renal glucose threshold – Raised HDL
Pregnancy	Fetal inheritance leads to a 550 g decrease in birth weight	HNF1A: – No fetal effect on birth weight HNF4A: – Possible fetal hypoglycemia – Increased risk of fetal macrosomia (fetal inheritance leads to a 800 g increase in birth weight)
Treatment	None, unless co-existent type 1 or type 2 diabetes	Sensitive to sulfonylurea treatment May progress to require insulin

Table 28.2 Differentiating β cell monogenic diabetes from type 1 and type 2 diabetes in young adults

Features	**Type 1 diabetes**	**Young-onset type 2 diabetes**	**GCK-MODY**	**TF-MODY**
Insulin dependent	Yes—after honeymoon	No	No	No
Parent affected	2–4%	60%	80%—but may not be diagnosed	80%
Usual age of onset	2 years—young adult	Adolescent and young adult	Birth (diagnosed at any age)	Adolescent and young adult
Obesity	Pop freq	>90%	Pop freq	Pop freq
Acanthosis nigricans	No	>75%	No	No
Glycemia	High	Variable—progressive	Mild stable	Variable—progressive
β-cell auto-antibodies	Positive in 80% of patients at diagnosis	No	No	No

GCK, glucokinase; *HNF1A*, hepatocyte nuclear factor 1A (*HNF4A* is similar); pop freq, the frequency seen in the general population.

significant microvascular complications [13]. The incidence of macrovascular complications appears similar to the background population.

Diagnosis

As *GCK* mutations cause mild asymptomatic hyperglycemia most cases of GCK-MODY are diagnosed following incidental testing of blood glucose, or following routine screening in pregnancy. A correct diagnosis is important in young people who might otherwise be thought to have type 1 diabetes. Persistent, stable mild hyperglycemia, lack of β-cell autoantibodies and mild hyperglycemia in a parent (when tested) all support a diagnosis of GCK-MODY. Differentiating GCK-MODY from T2DM can be more difficult; however, supporting clinical evidence for GCK-MODY includes lack of obesity or features of insulin resistance, or results obtained from an oral glucose tolerance test, when the glucose increment at 2 hours is usually <3 mmol L^{-1} [15]. Fasting plasma glucose below 5.5 mmol L^{-1} is rare in GCK-MODY outside pregnancy.

Treatment

Patients with GCK-MODY do not usually require treatment except in pregnancy (see later) [16]. If a patient is being treated with insulin or other hypoglycemic agents, it is usually possible to stop treatment when a diagnosis of GCK-MODY is made. However, if the HbA1c has ever exceeded 64 mmol L^{-1}, this should be done with caution, as it is possible for someone to have both a *GCK* mutation and type 1 or type 2 diabetes.

GCK-MODY and pregnancy

Women with *glucokinase* mutations are frequently first found to have hyperglycemia during screening in pregnancy. GCK-MODY represents about 3% of patients with gestational diabetes [17]. Correctly identifying GCK-MODY is important because these women have a different clinical course both within and outside pregnancy compared to "standard" gestational diabetes.

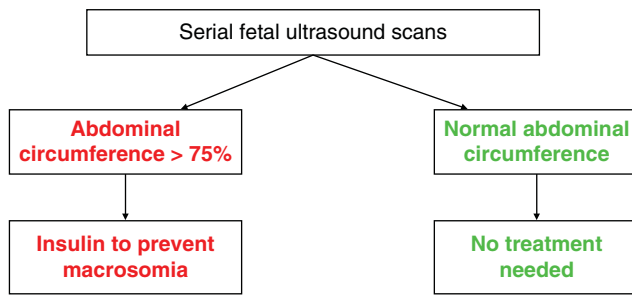
The aim of treatment of diabetes in pregnancy is to minimize the risk of fetal and maternal complications. This is usually achieved by strict control of the mother's blood glucose to prevent fetal macrosomia. However, in GCK-MODY pregnancies, the need to reduce maternal blood glucose is not absolute. This is because the fetus has a 50% chance of inheriting the *GCK* mutation from the mother, and the presence of the *GCK* mutation in the fetus influences the fetus' sensing of maternal glucose. Therefore, if the fetus does not inherit the *GCK* mutation it will respond to maternal hyperglycemia by excess insulin production and therefore excess growth, whereas if the fetus does inherit the *GCK* mutation it will sense the maternal hyperglycemia as normal, produce normal amounts of insulin and have normal growth (see Figure 28.4) [18]. In this latter setting, aggressively lowering maternal glycemia may adversely affect fetal growth [19]. As it is not usually possible to determine the fetal genotype, the decision on whether to treat the mother should be based on fetal growth. If the abdominal circumference is greater than the 75th centile insulin may be used but early delivery is the most successful strategy (see Figure 28.5).
Figure 28.4 Corrected mean birth weight for offspring of parents with glucokinase-MODY by category of maternal and fetal mutation status.


Figure 28.5 Suggested management of pregnancies of women with glucokinase-MODY based on fetal phenotype. Abdominal circumference is a surrogate for fetal inheritance.

A mother with a *GCK* mutation will need no pharmacologic treatment postpartum even if she has received very high insulin doses in pregnancy. This is in contrast to subjects with nonglucokinase gestational diabetes where deterioration to T2DM is usually seen over the following 10 years.

Transcription factor MODY

The majority of MODY genes encode transcription factors (TF). Transcription factors have an important role in regulating the expression of genes. They have a critical role in the variations in gene expression in the different stages of embryological development, and in different tissues. Transcription factors can also regulate expression of other transcription factors, thus establishing a complex regulatory network controlling gene expression.

Molecular genetics of TF-MODY

Hepatocyte nuclear factor-1α (HNF1A) was the first identified TF gene to cause MODY [20]. *HNF1A* is found on the long arm of chromosome 12 (12q), and mutations in *HNF1A* are the most common cause of MODY in the UK and most of Europe [2]. Nearly 200 mutations have been found scattered throughout the gene and consist of frameshift, missense, nonsense, and splice site mutations.

Transcription factor mutations alter insulin secretion in the mature β cell as well as altering β-cell development, proliferation, and cell death. Mutations in the hepatic nuclear factors appear to alter levels of proteins critical in metabolism including the GLUT2 glucose transporter and key enzymes in the mitochondrial metabolism of glucose [21,22].

Mutations in *HNF4A* are a much less common cause of MODY than *HNF1A* mutations, accounting for only 3% of MODY in the UK. Over 40 mutations have been described with the majority in the first four exons of the gene [23].

Mutations in the *HNF1B* gene cause renal cysts and diabetes syndrome and will be discussed under the heading "Diabetes with extra-pancreatic features" later in this chapter.

Other transcription factor mutations causing autosomal dominant β-cell diabetes have been identified in the following genes *PDX-1(IPF-1)*, *NEUROD1*, *PAX 4*, and *KLF11* but all are very rare and will not be described in this chapter [24–29].

HNF1A and HNF4A

From mouse models and *in vitro* studies in patients with TF-MODY, the development of diabetes and its deterioration with time is likely to be due to a metabolic defect in β-cell glycolysis and progressive loss of β-cell mass [30,31].

The pancreatic phenotypes in HNF1A-MODY and HNF4A-MODY have been the most studied of the TF-MODYs. It is striking that the different TFs causing MODY can have such differing nonpancreatic phenotypes (e.g. abnormal lipids, renal cysts) but have essentially the same pancreatic phenotype. The TFs causing MODY all form part of a regulatory network. Therefore, in the pancreas (but not in other tissues where an alternative HNF4A promoter is not used) there is a positive feedback loop established between HNF1A and HNF4A. It has been hypothesized that this feedback loop acts as a bistable switch that is only stable fully on or fully off. Therefore loss of function of HNF1A or HNF4A directly, or indirectly via *HNF1B* and *PDX-1* (IPF-1) mutations, will turn the switch to off thereby causing the same pancreatic phenotype whatever TF is mutated in this network [32]. The lack of this positive feedback switch in other tissues means that the nonpancreatic phenotype is determined by the role of the specific TF involved.

Phenotype of HNF1A and HNF4A

Heterozygous transcription factor mutations cause autosomal dominant diabetes presenting in adolescence or early adulthood resulting from progressive failure of insulin secretion. While diabetes is similar in HNF1A and HNF4A mutation carriers as a result of a common pattern of β-cell dysfunction, a number of differences in extrapancreatic features occur.

Common diabetes phenotype of HNF1A and HNF4A

The pancreatic phenotype in TF-MODY is characterized by:

(a) **β-Cell dysfunction**. The β-cell defect with reduced insulin secretion in response to stimulus has been shown in HNF1A- [33] and HNF4A-MODY [34] using graded glucose infusions. There is also marked loss of the first phase of insulin release in diabetic HNF1A subjects [3].

(b) **Progressive deterioration with time**. HNF1A-MODY subjects show a progressive deterioration in fasting plasma glucose with age [3]. This deterioration explains the increasing treatment requirements with time. Mouse studies [31,35] suggest that the deterioration is due to a decrease in β-cell mass with time. β-Cell loss is not auto-immune mediated as pancreatic autoantibodies are found in the same proportion as the nondiabetic general population.

In people with HNF1A- and HNF4A-MODY, diabetes usually develops in adolescence or early adult life. The youngest age of onset of diabetes in HNF1A-MODY reported is 4 years, with 63% of patients having developed diabetes by the age of 25; 79% by 35 years and 96% by 55 years. The mean age of diagnosis is similar in HNF1A- (20 years) and HNF4A-MODY (23 years) [36]. The age of diagnosis is in part related to the genetic mutations. In HNF1A there is evidence of imprinting

in utero, as the offspring inheriting the mutation of mothers with HNF1A diabetes during pregnancy have a younger age of onset than those mothers who develop the diabetes after their pregnancy.

Nondiabetes features of HNF1A and HNF4A
HNF1A
HNF1A-MODY patients are characterized by a low renal threshold for glucose. Hence glycosuria can occur at relatively mild levels of blood glucose (<8 mmol L^{-1}). Renal glycosuria has been shown to precede the development of diabetes and makes the screening of at-risk children by urinary screening for glycosuria an appropriate and sensitive screening test.

Despite patients with HNF1A-MODY having elevated levels of HDL, they also have an increased risk of cardiovascular disease compared with patients with T1DM. When compared with family members without HNF1A-MODY, those with a *HNF1A* mutation die at a younger age with a hazard ratio of 2.6 for cardiovascular death [37]. Frequency of microvascular complications is similar to that seen in type 1 and type 2 diabetes and relates to degree of glycemic control [38].

HNF4A
The offspring of *HNF4A* mutation-carrying mothers and fathers are at risk of marked macrosomia. There is on average an 800 g increase in birth weight compared with nonmutation-carrying siblings [39]. There is also an increased risk of hypoglycemia in affected neonates. These features appear to relate to increased insulin secretion *in utero* and in early infancy which evolves into reduced insulin secretion and diabetes in later life [39].

HNF4A-MODY patients have reduced concentrations of the apolipoproteins apoAII, apoCIII, and possibly apoB which are not seen in patients with T2DM [40,41]. Triglyceride levels are reduced in patients with HNF4A-MODY and probably reflect reduced lipoprotein lipase activity as a result of the reduced apolipoproteins [40].

Diagnosis of HNF1A and HNF4A
MODY should be considered in any person who develops diabetes at a young age. As genetic testing is currently too expensive for widespread use, the key diagnostic challenge is identifying TF-MODY in cases that would typically be labeled type 1 or type 2 diabetes. The key discriminatory clinical features are outlined in Table 28.3. As most patients with TF-MODY are diagnosed when young and do not typically have features associated with insulin resistance, they are most often labeled T1DM. Key suspicious features that would lead to molecular testing for TF-MODY include being β-cell autoantibody negative with a first-degree family relative with diabetes; no ketosis in the absence of insulin treatment; persistent insulin production (C-peptide) several years after diagnosis (post honeymoon) [42].

HNF1A- and HNF4A-MODY should be suspected in patients who have been labeled as having T2DM when there is a personal and family history of diabetes diagnosed at a young age (<25) and where there are no signs associated with insulin resistance (obesity, acanthosis nigricans).

Once MODY is suspected, a molecular genetic diagnosis should be sought. Clinical features can be used to target the gene analyzed. Although as HNF1A is more common than HNF4A a strategy in diagnostic testing is to test for HNF1A where there is reasonable clinical suspicion and only test for HNF4A in those who are negative for HNF1A.

In family members of those with an *HNF1A* or *HNF4A* mutation all family members with a pre-existing diagnosis of diabetes should have molecular genetic testing for the known mutation. In those without diabetes, it is usually sufficient to screen for diabetes using fasting plasma glucose. In young *HNF1A* mutation carriers (<20 years), the fasting plasma glucose can be normal, so testing urine for glycosuria can screen those where an oral glucose tolerance test is needed to confirm a diagnosis of diabetes; there is often a diabetic 2-h value, with a large increment between the fasting and 2-h plasma glucose [15].

Treatment of HNF1A and HNF4A
Most patients with a new diagnosis of HNF1A or HNF4A can be managed with dietary advice before requiring oral agents. When commencing oral agents the sensitivity to sulfonylureas means that these are the treatment of choice [43]. Even very low sulfonylurea doses may cause hypoglycemia. The starting dose should therefore be low—we use a starting dose of 40 mg gliclazide daily in adults. If there is hypoglycemia with low doses of sulfonylurea a short-acting agent such as nateglinide may be appropriate [44].

In those patients on treatment for a pre-existing diagnosis of type 1 or type 2 diabetes, the aim should be to switch to treatment with a sulfonylurea (if this is not already the case). Glycemic control and well-being with sulfonylureas is often better than on insulin and the fasting glucose-lowering effect is four times greater than that seen in T2DM [43]. Sulfonylurea treatment is successful in the majority of patients although a DP4 inhibitor or insulin therapy may be required as diabetes progresses [45].

In view of the increased risk of cardiovascular disease in HNF1A, statin therapy should be considered for all patients aged over 40 years; as in T1DM.

HNF1A and HNF4A in pregnancy
Evidence for the management of HNF1A and HNF4A in pregnancy is limited to case experience. As with all pregestational diabetes prenatal counseling is sensible to discuss and optimize treatment.

Sulfonylureas have been used successfully in HNF1A and HNF4A pregnancies with well-controlled diabetes. Given the greater clinical experience and pregnancy safety data with glibenclamide (glyburide) we recommend that women switch to this sulfonylurea prior to conception. If control remains suboptimal insulin treatment will be needed in addition.

Table 28.3 Causes and classification of neonatal diabetes

Pancreatic pathophysiology	Protein, chromosome, or gene affected	Prevalence	Inheritance	Features in addition to neonatal diabetes and low birth weight
Reduced β-cell function	KATP channel (*KCNJ11* and *ABCC8*)	35% of PNDM and 25% of TNDM	85% spontaneous. Remainder autosomal dominant or recessive	Developmental delay and epilepsy–genotype–phenotype correlation. (DEND and iDEND). Sulfonylurea responsive
	Chromosome 6q24	60% of TNDM	Variable	Macroglossia and umbilical hernia
	GCK (homozygous for mutation)	Rare cause of PNDM	Autosomal recessive	Both parents have GCK-MODY
	GLIS3	Rare cause of PNDM	Autosomal recessive	Congenital hypothyroidism, glaucoma, liver fibrosis, and cystic kidney disease
	SLC2A2	Rare cause of TNDM	Autosomal dominant or recessive	Thiamine-responsive megaloblastic anemia: hypergalactosemia, hepatic failure, neurologic deficit
Reduced pancreatic mass	*GATA6*	Rare cause of pancreatic aplasia	Autosomal dominant	Pancreatic agenesis and hypoplasia; cardiac malformations; developmental delay; gastrointestinal hernias
	PTF1A	Rare cause of pancreatic aplasia	Autosomal recessive	Pancreatic agenesis; cerebellar agenesis; developmental delay
	PDX1	Rare cause of pancreatic aplasia	Autosomal recessive	Pancreatic agenesis
	HNF1B	Rare cause of TNDM	Autosomal dominant	Exocrine pancreas insufficiency and renal cysts
Increased β-cell destruction	*INS*	12% of PNDM	Autosomal dominant	None
	EIF2AK3	30% of PNDM in consanguineous parents	Autosomal recessive	Wolcott–Rallison syndrome: spondylo-epiphyseal dysplasia, renal failure, recurrent hepatitis and mental retardation
	FOXP3	Rare cause of PNDM	X-linked	Immune dysregulation; thyroid autoimmunity; intractable diarrhea, eczematous skin rash, and elevated IgE

In pregnancies where either parent has an *HNF4A* mutation, the offspring is at increased risk of macrosomia and neonatal hypoglycemia if they inherit the mutation (a 50% chance) [46]. Given this, pregnancies need close monitoring with: very tight glucose control in mothers with diabetes; frequent fetal ultrasounds to monitor growth; early (even preterm) planned delivery if evidence of macrosomia; and monitoring of the newborn for hypoglycemia with consideration of diazoxide treatment, if hypoglycemia persists, according to published guidelines [47].

Unlike HNF4A, in pregnant women with HNF1A-MODY, fetal inheritance of the mutation does not affect outcome, so treatment should focus on controlling maternal hyperglycemia to reduce the risk of macrosomia.

Neonatal diabetes: diabetes diagnosed within 6 months of life

Neonatal diabetes (NDM) is defined as monogenic β-cell diabetes which is diagnosed in the first six months of life. It is rare, affecting one in 200,000 live births [48]. The evidence that a diagnosis before 6 months is the cut-off between monogenic

neonatal diabetes rather than polygenic T1DM comes from studies of high-risk type 1 HLA, antibodies, birth weight (reduced before 6 months suggests a reduced insulin secretion *in utero*) and monogenic genetic studies [49–52].

Clinical features

Patients may be detected when glucose is tested in the first few days of life in low-birth weight babies or may present later when the patient is severely unwell with ketoacidosis. Patients are severely insulin deficient and C-peptide is usually not detectable. Approximately 30–40% of cases remit spontaneously and are referred to as transient neonatal diabetes mellitus (TNDM) as opposed to permanent neonatal diabetes mellitus (PNDM) where diabetes persists. TNDM often recurs between the first and third decades of life [53]. Thirteen genes involved in β-cell development, survival, or function have been implicated in the development of neonatal diabetes. Table 28.3 summarizes the known genetic causes of neonatal diabetes.

Permanent neonatal diabetes
Molecular genetics
Over a third of NDM is caused by mutations in the genes *KCNJ11* and *ABCC8*. These encode the Kir6.2 and SUR1 subunits, respectively, of the β cell ATP-sensitive potassium channel (K_{ATP} channel) [54–57]. Normally, the K_{ATP} channel closes in response to raised intracellular ATP levels that occur as blood glucose rises. Channel closure causes depolarization of the β-cell membrane which results in insulin secretion. Activating mutations in *KCNJ11* and *ABCC8* prevent the K_{ATP} channel closing, in response to increased ATP, preventing insulin release [58].

The K_{ATP} channel is also present in the brain, nerves, and muscles. In those with more functionally severe *KCNJ11* mutations (∼20% patients), and occasional patients with *ABCC8* mutations, there is associated neurodevelopmental delay [52,54,55,58].

The majority (80%) of PNDM resulting from K_{ATP} channel mutations arise spontaneously from *de novo* heterozygous mutations, with the remainder inherited mainly in an autosomal dominant pattern. About 25–40% of neonatal diabetes resulting from *ABCC8* mutations is inherited in an autosomal recessive fashion [57].

Heterozygous mutations in the insulin gene (*INS*) have been identified in 10% of cases of neonatal diabetes [59]. *EIF2AK3* recessive mutations cause Wolcott–Rallison syndrome and are the commonest cause of neonatal diabetes when the parents are consanguineous and account for 24% of these cases [60]. A number of other genetic causes have been found which all are relatively rare as outlined in Table 28.3 [61].

Clinical features of the common subtypes of permanent neonatal diabetes
Neonatal diabetes, caused by *KCNJ11*, *ABCC8*, and *INS* mutations, typically present within the first six months of life (median 6–10 weeks). Infants are unwell, failing to thrive, with marked hyperglycemia often accompanied by ketosis.

C-peptide is usually undetectable and pancreatic autoantibodies negative [54]. Birth weight is low (∼2.5 kg) as a result of reduced insulin secretion *in utero* with consequent decreased insulin-mediated growth.

About 20% of patients with PNDM and *KCNJ11* mutations have neurologic features, the commonest being developmental delay, sometimes with muscle weakness and/or epilepsy. The most severe form where neonatal diabetes is accompanied by developmental delay and epilepsy has been named "DEND" (developmental delay, epilepsy, and neonatal diabetes). "Intermediate DEND" (iDEND) refers to neonatal diabetes with less severe developmental delay. The severity of the clinical condition relates closely to the underlying mutation and its effect on K_{ATP} channel ATP sensitivity [58,62].

Neonatal diabetes caused by *ABCC8* mutations leads to TNDM almost as often as PNDM and rarely has associated neurodevelopmental features [55–57]. Neonatal diabetes due to *INS* mutations causes PNDM but patients do not have extrapancreatic features [63].

Patients with Wolcott–Rallison syndrome typically develop diabetes before six months, and skeletal dysplasia occurs within the first two years of life. Other manifestations vary between patients in their nature and severity and include frequent episodes of acute liver failure, renal dysfunction, exocrine pancreas insufficiency, intellectual deficit, hypothyroidism, neutropenia, and recurrent infections [60,64].

Treatment of permanent neonatal diabetes
At diagnosis of neonatal diabetes, all patients should be commenced on insulin treatment to stabilize blood sugars. All patients with neonatal diabetes should be referred for urgent molecular genetic testing, results of which should be available within a week. This is because over a third of patients will have a K_{ATP}-channel mutation (*KCNJ11* or *ABCC8*) the majority of whom can successfully transfer from insulin to sulfonylurea therapy; 90% of those with *KCNJ11* mutations are able to discontinue insulin. There are usually significant improvements in glycemic control without an increase in hypoglycemia [56,65]. Sulfonylureas work by closing the β cell K_{ATP} channel by an ATP-independent route thus allowing β-cell depolarization and insulin release [65].

Glibenclamide has been used in the majority of NDM cases. It was initially used as it is nonselective and widely available; however there is evidence that it may be more effective than other sulfonylurea agents [66]. The doses needed are higher than those needed for the treatment of T2DM: a median dose of $0.45\,mg\,kg^{-1}$ per day is required with doses up to $1.5\,mg\,kg^{-1}\,d^{-1}$ needed in some cases [65,67]. Sulfonylurea therapy may result in some improvement in neurologic features even when they are commenced in adulthood [66,68,69].

All other causes of neonatal diabetes need treatment with insulin. A molecular genetic diagnosis is still important as it will inform on extrapancreatic clinical features and allow genetic counseling [70].

Table 28.4 Characteristics of diabetes with extrapancreatic features

Syndrome	Gene defect	Extrapancreatic clinical features
Renal cysts and diabetes (**RCAD**)	*HNF1B*	Renal cysts or renal development disorders Short stature Genito-urinary abnormalities Hyperuricemia and gout Hypermagnesemia Abnormal liver function tests
Mitochondrial diabetes and deafness (**MIDD**)	*m3243A>G*	Maternal inheritance Neurosensory deafness Pigmentary retinal dystrophy Nephropathy Neuromuscular features
Wolfram syndrome (also known as DIDMOAD)	*WFS1*	**D**iabetes **I**nsipidus, **D**iabetes **M**ellitus, **O**ptic Atrophy and **D**eafness Degenerative neurologic disease Dilated nephropathy

Transient neonatal diabetes

Molecular genetics

The genetic etiology of more than 80% of transient neonatal diabetes has been established. The commonest cause is abnormalities in the q24 region of chromosome 6 (6q24) affecting imprinted genes [61,71]. Genetic imprinting occurs when only the maternal or paternally inherited allele of a gene is expressed. In TNDM, paternal uniparental disomy, paternal duplication of 6q24 or abnormal methylation of the maternal copy of the chromosome causes overexpression of the paternal copies of the genes *PLAGL1* (also known as *ZAC*) and *HYMAI* [71,72]. Paternal duplication of 6q24 can be inherited; therefore this abnormality causes the majority of inherited TNDM cases. Uniparental disomy causes sporadic TNDM; cases resulting from abnormal methylation of the maternal copy of chromosome 6 may be sporadic or inherited [71,72]. The majority of TNDM not associated with 6q24 abnormalities are caused by mutations in *KCNJ11* and *ABCC8* [52,53,56,73–76].

Clinical features of transient neonatal diabetes

6q24 diabetes usually presents in the first week of life. Neonates often have severe hyperglycemia and dehydration but are usually not ketotic [71]. Islet cell antibodies are usually negative and C-peptide is low or negligible [71]. Low birth weight is common (mean birth weight 2 kg), and there may be associated macroglossia and/or umbilical hernia. Insulin treatment is required for a median of 12 weeks before the patient goes into remission. Diabetes recurs later in life in 50–60% of patients as a result of pancreatic β-cell dysfunction. The average age of recurrence is 14 years. In some cases hyperglycemia may be intermittent and seen only at times of stress [71,77].

Where TNDM is caused by *KCNJ11* and *ABCC8* mutations, diabetes tends to present later (median 4 weeks), takes longer to remit, and is associated with less intrauterine growth restriction (median birth weight 2.6 kg). Remission occurs in about 50% of patients and tends to occur in the first decade (median 4.7 years (3–15)) [53].

Management of transient neonatal diabetes

Insulin is required at diagnosis in the neonatal period; however, on relapse in later life, treatment requirements vary: diet; oral hypoglycemic agents or insulin [77]. In TNDM cases that result from *KCNJ11* or *ABCC8* mutations, infants may be switched from insulin to sulfonylurea treatment [53,56]. The sulfonylurea doses required are lower than for infants with K_{ATP}-channel mutations causing PNDM and care should be given to monitor for hypoglycemia.

Genetic counseling depends on the underlying genetic etiology. Cases caused by uniparental disomy are sporadic and therefore have low risk of occurrence in either siblings or offspring of the affected child. Methylation defects often result from homozygous mutations in the transcription factor gene ZFP57 and therefore may be inherited in an autosomal recessive manner [72]. Offspring of males with 6q24 duplication have a 50% chance of developing TNDM whereas if the abnormality is inherited from the mother they will not be affected but the TNDM may occur in the following generation [77].

Genetic testing in neonatal diabetes

At the time of diagnosis of neonatal diabetes it is not known whether diabetes will be transient or permanent. We advise testing for 6q24 abnormalities, *KCNJ11*, *ABCC8*, and *INS* mutations at diagnosis in all diabetes diagnosed before 6 months. Identifying mutations in these genes is important as it will influence treatment. An early diagnosis and very low birth weight make 6q24 most likely. A genetic cause (*KCNJ11* or *INS*)

can be established in approximately 7% of diabetes diagnosed between 6 months and 1 year of age so consideration should be given to testing this age group, especially where autoantibody tests are negative [51].

Diabetes with extra-pancreatic features

Renal cysts and diabetes (RCAD) syndrome: HNF1B-MODY

Molecular genetics of RCAD
HNF1B is a transcription factor with a role in regulating gene expression in a number of tissues. HNF1B forms homo and heterodimers with *HNF1A*, is present in similar tissues although at different levels, and binds to the same DNA consensus sequence. Despite these similarities *HNF1B* mutations cause diabetes by a different mechanism and have a distinct phenotype. There is autosomal dominant inheritance, although up to 50% of cases arise from *de novo* mutations or deletions.

Phenotype of RCAD
The predominant phenotype in *HNF1B* mutations is that of nondiabetic developmental renal disease, most frequently resulting in renal cysts, and diabetes is a less consistent finding. The association of renal cysts with diabetes in *HNF1B* mutations has led to the designation "Renal Cysts and Diabetes" (RCAD) syndrome [78].

Developmental abnormalities can also be seen in the genital tract, liver, and gut. Uterine and genital tract abnormalities have been described in about 30% of patients [79]. The reason for this is that HNF1B is expressed earlier in embryogenesis and it has a role in regulating gene expression in a number of tissues including the pancreas, kidneys, liver, genital tract, and gut [80]. Birth weight is reduced by around 800 g as a result of reduced insulin secretion *in utero* [81]. Atrophy of the pancreatic tail can be seen on radiologic scan; associated with loss of pancreatic exocrine function [82] (see Table 28.4).

Most cases of *HNF1B* mutations present to the renal physicians as the varied renal phenotype usually precedes the onset of diabetes. The most common renal phenotype is developmental renal disease, most commonly renal cysts. Renal cysts are present in >75% of patients with *HNF1B* mutations and are frequently seen on antenatal scanning [51,83]. Three discreet renal histologies have been described: cystic dysplasia, oligomeganephronia, and familial hypoplastic glomerulocystic kidney disease [83]. There are varying degrees of renal dysfunction with approximately 50% of patients ultimately requiring dialysis or transplantation for end-stage renal failure. There is also an association with chromophobe renal cell carcinoma. The severity of the renal disease does not correlate with the genotype [84]. Hypomagnesemia, hyperuricemia, and familial hyperuricemic nephropathy [85–87] have also been described and may reflect a specific defect in renal tubular transport.

In marked contrast to HNF1A-MODY, the diabetic people with RCAD have insulin resistance with hypertriglyceridemia.

Approximately 50% of cases of RCAD are due to 17q12 gene deletions, and there can be associated learning disability and autism [88].

Diagnosis of RCAD
Testing for RCAD should be considered where there is unexplained renal cystic disease (or other renal developmental disease) with or without genito-urinary tract abnormalities or diabetes. As about half the cases of RCAD are spontaneous, lack of a family history should not be a barrier to testing. Testing should not be done in the presence of simple renal cysts and typical type 1 or type 2 diabetes as both conditions are common in the general population. As heterozygous deletions or mutations can cause HNF1B-MODY it is important that copy number analysis, as well as sequencing, is performed when seeking a diagnosis.

Treatment of RCAD
Renal disease needs to be managed as any other chronic renal condition, with periodic monitoring of renal function and treatment as appropriate. In addition biennial ultrasounds are recommended to screen for chromophobe renal carcinoma. Patients with diabetes are not sensitive to sulfonylurea therapy and are best treated with insulin.

Mitochondrial diabetes
Mitochondria play an essential role in generating chemical energy for cells. Individual cells often contain a variable mixture of mutated and normal mtDNA—termed heteroplasmy. The degree of heteroplasmy varies between tissues and within families and this explains the varied phenotypes seen with the same mitochondrial mutation. Mitochondrial mutations are inherited maternally, as during fertilization the mitochondria in the tail of the sperm do not enter the oocyte.

Maternally inherited diabetes and deafness (MIDD) is the most common mitochondrial diabetes syndrome and will be discussed in the following section. A number of other mitochondrial mutations have been described in families with maternally inherited diabetes (with or without deafness); these are rare (reviewed in [89]).

Maternally inherited diabetes and deafness (MIDD)
Maternally inherited diabetes and deafness (MIDD) most commonly results from heteroplasmic G to A substitution of the mitochondrial DNA at nucleotide pair 3243 in one of the two tRNA(Leu) genes [90].

The same mutation that causes MIDD (m.3243A>G) also causes a syndrome of severe neuromuscular disease called MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke). Within a family there is usually a dominant phenotype, although occasionally some members develop MIDD whilst others develop MELAS [91]. Most subjects with

MELAS do not develop diabetes, although it has been described. It is not clear why some m.3243A>G carriers develop MIDD whereas others develop MELAS, but it would appear that they are two distinct but overlapping syndromes.

The prevalence of MIDD was 1.3% in a cross-sectional study of the diabetic population in the Netherlands [92]. All children of a mother with an m.3243A>G mutation will inherit the mutation, to some extent. However, only 60% of 3243 mutation carriers will develop diabetes, the remainder seem to have normal glycemic profiles during OGTT in middle age [92]. Spontaneous 3243 mutations have been described, so a lack of family history of diabetes or deafness does not exclude MIDD.

Phenotype of MIDD

Diabetes usually develops insidiously in the third to the fifth decade, although the age of presentation is variable, and a fifth of patients present acutely. Pancreatic autoantibodies are usually negative [93]. Over 75% of diabetic m.3243A>G mutation carriers have sensorineural deafness, though this may reflect diagnostic bias (i.e., testing those with diabetes and deafness) [91]. The deafness may present after the diabetes; however, it is usually present in other family members to raise suspicion of MIDD. Hearing loss is more common and more marked in men than women; it is usually loss of high-frequency perception and often requires use of a hearing aid [92] (see Table 28.4).

Other features of MIDD reflect the overlap of this syndrome with MELAS. Neuromuscular signs especially myopathy, high serum lactate or lactate:pyruvate ratio, nephropathy, cardiac problems with ECG abnormalities, and spontaneous abortions are described [92,93]. Many patients with m.3243A>G mutations have pigmentary retinal dystrophy, although this does not usually affect vision. Patients with MIDD have a high prevalence of renal disease leading to end-stage renal failure, although this can in part be attributed to diabetic nephropathy. The most common histologic finding is of focal segmental glomerular sclerosis, this can predate the diabetes or deafness.

Diagnosis of MIDD

The suspicion of MIDD should be raised in any family with diabetes, deafness, or other unusual neurologic features. Diagnosis is made by confirmation of a mitochondrial DNA defect at position 3243. Low heteroplasmy levels in blood can, however, mean that a mitochondrial mutation is missed. If clinical suspicion is high then the molecular diagnosis should be repeated on DNA from urine or oral mucosa, where the heteroplasmy rates are higher.

Treatment of MIDD

Most patients are treated with diet and oral agents at first although there tends to be a rapid progression to insulin, being started at a mean of 2 years after diagnosis. Metformin should probably be avoided because of the overlap with MELAS and risk of metformin precipitating lactic acidosis.

Coenzyme Q10 has been shown to improve respiratory chain function in mitochondria with the m.3243A>G mutation.

Anecdotal case reports suggest coenzyme Q10 may prevent hearing loss and delay diabetes in MIDD without side effects, although they mostly just show some improvement in muscle function and lactic acid accumulation on exercise. Maintaining sufficient thiamine intake is thought to be important to optimize mitochondrial function.

Wolfram syndrome

Wolfram syndrome is also referred to as DIDMOAD due to the usual occurrence of **D**iabetes **I**nsipidus, **D**iabetes **M**ellitus, **O**ptic Atrophy, and **D**eafness, although only the presence of diabetes mellitus and bilateral progressive optic atrophy are necessary to make the diagnosis of Wolfram syndrome. The syndrome is rare, with a prevalence of 1.3 per million population in the UK [94].

Molecular genetics of Wolfram syndrome

Wolfram syndrome is an autosomal recessive disorder with consanguinity of patients' parents being common. It is caused by mutation in the *WFS1* gene or Wolframin in over 90% of patients [95] and rarely missense mutations in the *CISD2* gene [96].

Clinical features of Wolfram syndrome

Two case series, comprising about 100 individuals with Wolfram syndrome have given a clear clinical phenotype [94,97]. Diabetes mellitus was the commonest presenting feature (diagnosis median age 6 yrs (range 3 weeks – 16 yrs); 95% were treated with insulin at outset, and C-peptide was low or undetectable. Optic atrophy was diagnosed at a median age of 10 years (range 3 – 30 yrs) and progresses to blindness in most patients. Deafness was present in (46 – 62%) of patients.

Other features were less common and usually presented later: 50% have diabetes insipidus; 55% renal tract abnormalities (dilated renal outflow tracts and bladder atony); 55% neurologic abnormalities. Males frequently had primary gonadal atrophy and females had menstrual irregularity and delayed menarche but have conceived normal children [94]. There is a high mortality with a median age of death in the UK series of 30 years (range 25 – 49). The most common causes of death were respiratory failure or dysphagia due to brainstem involvement (see Table 28.4).

Diagnosis and treatment of Wolfram syndrome

The development of optic atrophy in a young person with insulin-treated diabetes mellitus should raise suspicion of Wolfram syndrome. Other clinical features should be sought and the diagnosis confirmed by molecular genetic analysis, with direct sequencing of the *WFS1* gene. There is no treatment to alter outcome of the disease. Diabetes requires insulin treatment with other symptoms being treated as required.

Using molecular genetics in diabetes care

In monogenic β-cell diabetes the importance of making a correct diagnosis has seen molecular genetic sequencing move

rapidly from a research tool to clinical care. The use of diagnostic molecular genetics results in new challenges for the clinical diabetes team. Tests are expensive and need to be performed in the patients where monogenic diabetes is most likely. Genetic results need to be correctly reported and interpreted [98]. A molecular genetic diagnosis in a patient needs to be followed by appropriate treatment change and clinical follow-up and also appropriate testing (both biochemical and genetic) for family members.

This change in clinical practice needs to occur in a specialty where there has been very little training in genetics. A source of valuable information for doctors, nurses, and patients can be found at www.diabetesgenes.org.

Immunopathogenesis of type 1 diabetes in Western society

Alberto Pugliese

Immunology and Microbiology, Division of Diabetes, Endocrinology and Metabolism; Immunogenetics Program, Diabetes Research Institute, University of Miami Miller School of Medicine, Miami, FL, USA

Key points

- Islet autoimmunity appears to be the dominant pathogenic mechanism leading to β-cell loss. Autoimmunity may persist or become reactivated throughout the diabetes clinical spectrum, even decades after diagnosis, for instance when patients receive a pancreas or islet transplant, and favor graft loss.

- Early in life, genetic predisposition impacts the development of thymic tolerance to selected autoantigens. This may represent the earliest pathogenic event; true primary prevention strategies to promote self-tolerance should be instituted in early life, perhaps even during gestation.

- Dysregulation of peripheral immune regulation occurs at multiple levels, promoted by both genetic predisposition and inflammation, in turn amplified by environmental exposures. Many impaired pathways of peripheral immune regulation, as well as inflammation, are being targeted with specific drugs in clinical trials.

- The discovery of several target antigens and the improved understanding of the molecular interactions among antigen-presenting molecules, peptide antigens, and T-cell receptors are facilitating progress towards antigen-specific therapies to selectively delete or regulate autoreactive T cells.

- A critical gap in our understanding of the disease pathogenesis stems from our inability to assess pathology in the pancreas in relation to secretory function. However, growing evidence suggests that loss of β-cell loss and impaired insulin secretion are less severe than previously thought, pointing at additional pathogenic factors and suggesting a wider therapeutic window to reverse diabetes.

Introduction

Type 1 diabetes (T1DM), formerly referred to as insulin-dependent diabetes mellitus (IDDM) and juvenile diabetes, is considered a chronic autoimmune disease. Over time, the disease process results in the virtually complete elimination of pancreatic β cells and lifelong insulin deficiency. In turn, patients become dependent on daily insulin injections to maintain an acceptable level of metabolic control. It is widely accepted that T1DM is a complex, multifactorial disease in which genetic predisposition and environmental exposures promote the triggering of multiple autoimmune responses against β cells.

While a variety of putative environmental factors have been described [1], including infectious agents, dietary and other factors, true etiologic/triggering environmental agents and causal mechanisms remain to be identified. On the other hand, several susceptibility loci have been identified, and many mapped to known genes with predominant function or effects on immune mechanisms, largely supporting a dominant role for an immune-mediated pathogenesis. This is corroborated by the presence of both humoral and cellular autoimmune responses against several islet cell autoantigens near the time of diagnosis. Moreover, in prospective studies, similar responses are observed in nondiabetic first-degree relatives preceding disease development. The most extensively studied autoantigens include insulin/proinsulin, glutamic acid decarboxylase (GAD65), the tyrosine phosphatase-like protein IA-2, the islet-specific glucose-6-phosphatase catalytic subunit-related protein (IGRP), and the cation efflux transporter ZnT8 [2]. Standardized radio-immunoassays measure autoantibodies to insulin, GAD65, IA-2, and ZnT8, which are diagnostic and predictive markers employed as screening tools in natural history studies and prevention trials [3].

The disease commonly develops in children or adolescents, with incidence peaking around 10–14 years of age [4]. Prospective studies in genetically at-risk cohorts demonstrate that islet autoimmunity can be triggered during early childhood [5]. However, T1DM is also diagnosed in adults [4]. Some adult patients with milder presentation are diagnosed with latent onset diabetes of the adult (LADA); it has been proposed that

LADA may fundamentally be a clinical expression of T1DM characterized by later triggering and/or slower progression [6], perhaps occurring in individuals with attenuated genetic susceptibility [7]. The disease incidence and prevalence vary in children from different countries and populations within an approximate 350-fold spread [4]. The lowest incidence rates (0.1–1/100,000) are reported in Asian populations (China, Japan) and some South American countries. The highest incidence rates, ranging from 5 to 60/100,000, are reported in Caucasian populations of the Western world [8]. Northern European countries such as Finland and Sweden have very high incidence and prevalence, but a similarly high incidence is reported in Sardinia, an island in the Mediterranean Sea [9]. During the past few decades the worldwide disease incidence has been rising 2–5% annually, albeit not uniformly in various countries and throughout time periods [8]. Moreover, many studies indicate that T1DM is becoming more common in younger children (<5 years old) [4,8,10]. The prevalence of T1DM in the United States, where the population comprises multiple racial and ethnic groups, is approximately 1/300 by age 18; data from the SEARCH study indicate that incidence and prevalence rates are higher (roughly by 30–50%, depending on ethnic and age groups compared) in non-Hispanic whites (>20/100,000 in youth less than 20 years old) compared to Hispanic, African Americans, and American Indians [4].

Overall, epidemiologic data show that T1DM is more prevalent in the Western world, especially affecting, albeit not exclusively, Caucasians of Northern European descent. This chapter focuses on reviewing recent and major findings about the disease pathogenesis that are largely originated by studies in patients from the Western society.

Genetic studies provide clues about key disease mechanisms

Genetic predisposition is an important component of the multifactorial pathogenesis of T1DM. Although often diagnosed in individuals with no known family history of T1DM, the disease is about 15 times more common in siblings of a patient than in the general population. Siblings have an average risk of 6%, although individual risk varies significantly in relation to the extent of sharing predisposing genes with the proband, which allele variants are shared, and other factors. The risk to the offspring of affected mothers and fathers is about 2–3% and 6–7%, respectively [4]. Among twins, the observed disease concordance rates are approximately 8–10% in dizygotic twins and, with extended follow-up, more than 60% in monozygotic twins [11].

Extensive genetic studies have been conducted during the past decades in thousands of families with affected sibling pairs, family trios, patients, and unrelated controls, including genome-wide association studies. The largest coordinated efforts were led by the Type 1 Diabetes Genetic Consortium (www.T1DGC.org), an international collaboration [12]. A single, major susceptibility locus and a multiplicity of other loci (upwards of 50; see http://www.t1dbase.org), individually conferring a much smaller risk, have been identified [12]; indeed, only four of these genes (HLA Class II, insulin, PTPN22, and IL2RA) are associated with odds ratios greater than 1.5 [12]. Several, but not all, of the genetic loci associated with T1DM have been confirmed in multiple data sets and populations [13]. Many if not most of the susceptibility loci mapped to known genes encode for proteins involved in immune function; a few other genes are expressed in pancreatic islets and putative risk genes remain to be mapped at some recently associated loci [12]. Besides inherited alleles, additional mechanisms may regulate gene expression and function, including epigenetic regulation, typically mediated by changes in DNA methylation [14]; in addition to contributing to susceptibility, epigenetic regulation may represent a mechanism by which gene–environment interactions can impact disease risk and could help explaining the significant increase in disease incidence reported in many populations [15]. In the next paragraphs we will discuss putative disease mechanisms associated with the best studied risk genes. Figure 29.1 illustrates these mechanisms and compares the effects of predisposing and protective gene variants at the HLA-DQ, insulin, PTPN22, CTLA-4, IL2RA, and IHIF1 loci.

HLA-encoded genetic predisposition points at adaptive autoimmune responses as the dominant effector mechanism leading to β-cell destruction. As noted, the identification of several susceptibility genes involved in key immunologic functions supports a key role for autoimmunity in the disease pathogenesis. Many of these genes control critical functions of the adaptive immune system, in particular, T-cell responses and their regulation. Experimental evidence points at T cells as the main effectors of β-cell destruction. Accordingly, the primary susceptibility locus maps to the human leukocyte antigen (HLA) complex, specifically to HLA class II and class I antigen-presenting molecules; these function as restricting elements for CD4 and CD8 T-cell responses, respectively. HLA-encoded susceptibility confers up to 50–60% of the overall genetic risk from inherited alleles [16].

Within the HLA complex, HLA class II loci have the strongest association with disease risk; in particular, the HLA-DR3, DQA1*0501-DQB1*0201 (DQ2) and HLA-DR4, DQA1*0301-DQB1*0302 (DQ8) genotype is the strongest susceptibility factor with an odds ratio >40 [12]. This genotype is typically carried by 30–50% of patients, compared to about 2% of the general population; most patients carry at least one of these two high-risk haplotypes. The higher risk conferred by the heterozygous genotype is explained by the formation of a trans-complementing HLA-DQ heterodimer, which can only be formed when the two haplotypes are inherited together, that is capable of presenting islet autoantigens and promote diabetogenic responses [17]. On the other hand, HLA-DR4, DQA1*0301-DQB1*0301 (DQ7) haplotypes are considered neutral. This observation links diabetes risk with the DQB1*0302 chain. In contrast, HLA-DR2 (DRB1*1501)
Figure 29.1 Best characterized genetic mechanisms that influence islet autoimmunity. The figure illustrates and contrasts the molecular mechanisms underlying genetic susceptibility and genetic protection for well-characterized loci (HLA, insulin, PTPN22, CTLA-4, IL2RA, and IHIF1). The interaction between a CD4 T cell and an antigen-presenting cell (APC) is used to depict these mechanisms.
HLA class I/II: presentation of autoantigen peptides to CD8/CD4 T cells in thymus and periphery is influenced by the HLA variant;
Insulin: predisposing variants of the insulin gene VNTR are linked to reduced insulin expression in thymus, and in turn to impaired negative selection of insulin-specific T cells;
PTPN22 (Lyp): the predisposing variant identified at this locus is a gain of function mutant, resulting in increased inhibition and impaired TCR signaling, which may affect multiple processes including thymic selection of T cells;
CTLA-4: predisposing variants associated with reduced levels of sCTLA-4, may impair control over T-cell activation through effects on regulatory T cells;
IL2RA: predisposing variants associated with low levels of sIL2RA, reduced STAT5a responses in antigen-experienced CD4 T cells, and impaired regulatory T-cell function with decreased expression of the FOXP3 transcription factor (not illustrated);
IFIH1: predisposition is associated with increased expression of IFIH1, IFN, and NFκB responses, cytokines, and an overall enhanced inflammatory response from APCs, following recognition of viral RNAs; this locus links susceptibility to viral infections.

haplotypes carrying DQA1*0102-DQB1*0602 are negatively associated with T1DM in several populations, with less than 1% of T1DM patients carrying this protective haplotype; reportedly, this haplotype confers strong protection from T1DM development also in first-degree relatives with autoantibodies [18].

Several HLA-DR4 subtypes are defined by polymorphisms of the DRB1 chain, for example DRB1*0401, DRB1*0404, and so on, and they show variable degrees of association with T1DM risk, even when in linkage with DQA1*0301-DQB1*0302; this suggests that the HLA-DRB1 molecule also plays an important role in modulating immune responsiveness to islet antigens [16]. While there is significant linkage disequilibrium across

the HLA complex, selected HLA class I alleles are also associated with T1DM, independently of class II genes, especially HLA-A2, HLA-A24, and HLA-B39 [19]. Many studies suggest that additional loci within the HLA complex may modulate susceptibility. The largest and most systematic evaluation was conducted by the T1DGC, which reported data for more than 3000 single nucleotide polymorphisms, 66 microsatellites, and class I and class II DNA-based allele typing data in 2300 families with affected sibling pairs; these studies identified several associations involving many genes within the HLA complex, suggesting that HLA-encoded susceptibility derives from multilocus effects [20].

Genetic predisposition impacts central immune tolerance to islet cell antigens. Antigen presentation by HLA molecules is not only a key to the activation of adaptive immune responses, but also to the generation of regulatory T cells and the stimulation of other regulatory mechanisms. Antigen presentation is also required for T-cell selection processes occurring in the thymus during the maturation of the immune system to establish immunologic self-tolerance. Genetic predisposition can impair central (thymic) tolerance to selected autoantigens, and this may well represent the earliest event in T1DM pathogenesis.

Such mechanisms became apparent following the discovery that peripheral or tissue-restricted antigens (TRAs) from multiple organs are "ectopically" produced in the thymus to support the development of immunologic self-tolerance in early life [21]. TRA expression in the thymus is primarily mediated by medullary thymic epithelial cells (mTECs), which transcribe many TRA genes under the control of the AIRE autoimmune regulator transcription factor [22]. Thymic CD11c$^+$ dendritic cells (DCs) also express insulin and other TRAs [23], but TRA expression levels are lower in DCs compared to mTECs [24]. DCs can also uptake antigens produced by mTECs [25], a function that is also supported by AIRE [22].

Insulin itself is a prototypical TRA, its synthesis being virtually restricted to pancreatic β cells. Thymic insulin production is critical for establishing self-tolerance to β cells; simply abolishing insulin expression in the thymus leads to the rapid onset of autoimmune diabetes even in mice lacking a diabetogenic genetic background [26]. In humans, thymic insulin expression is modulated by allelic variation and epigenetic effects at the insulin gene locus; this effect is largely mediated by a polymorphic variable nucleotide tandem repeat (VNTR) sequence. In the thymus, protective VNTR alleles are associated with 2.5- to 3-fold higher insulin gene transcription levels compared to predisposing alleles [27,28]; polymorphisms of the AIRE and MafA transcription factors also modulate insulin gene transcription in the thymus [29,30]. As with other self-molecules, thymic insulin levels impact negative selection of autoreactive T cells and/or positive selection of regulatory T cells; lower levels typically lead to less efficient selection processes, promoting the maturation of a T-cell repertoire that is enriched in insulin autoreactive T cells [31].

Immunologic tolerance to other islet autoantigens is likely shaped by thymic expression as well: splice variants of the IA-2 and IGRP islet autoantigens have expression patterns that differ in human pancreas and thymus, suggesting that self-tolerance to antigenic epitopes expressed only in the pancreas may not be fully achievable [32,33]. Thus, allelic variation, alternative splicing, and epigenetic regulation of gene expression can affect quantity and quality of TRA expression in the thymus, in turn impacting thymic selection processes and favoring the maturation of a T-cell repertoire that is prone to autoimmune responses to a variety of islet autoantigens.

Escape from negative selection may also be favored, albeit not in an antigen-specific fashion, by polymorphisms of the PTPN22 gene. This encodes for Lyp, an intracellular, lymphocyte-specific tyrosine phosphatase, which functions as a negative regulator of TCR signaling. PTPN22 predisposition may derive from more potent suppression of TCR signaling during thymic development, resulting in impaired negative selection [34]. Furthermore, recent investigations of patients' autoreactive CD4 T cells highlight abnormal features of the immunologic synapses that may also favor escape from negative selection and promote effector responses in the target organ, where larger amounts of antigen are present [35].

Overall, there is strong evidence that the earliest disease mechanisms and primary genetic predisposition effects are active in early life, through modulation of thymic selection processes, with the stronger effects likely being specific for selected islet cell molecules, primarily under the genetic control of HLA and insulin genes. Therefore, true primary prevention strategies should aim at improving the efficiency of thymic selection processes and should be attempted very early, perhaps *in utero*. For example, drugs are being sought to enhance thymic insulin expression [36], which could be given to genetically at-risk children if safe and effective.

Functional properties of HLA class II and class I molecules presenting diabetogenic peptides. As noted, HLA class I and class II molecules mediate TRA presentation to developing lymphocytes in the thymus. In patients with T1DM, these will commonly be the predisposing variants described earlier. Molecular studies reveal that certain amino acid residues impact the peptide binding properties of these molecules and in turn presentation of islet antigen peptides to autoreactive T cells; for example, DQB1*0302 carries a serine at position 57, where most nonpredisposing HLA-DQ molecules carry an aspartic acid residue [37]. There are remarkable sequence (including position 57) and structural similarities between the human HLA-DQ8 molecule and its homologous I-Ag7 in the MHC (major histocompatibility complex) of the NOD (nonobese diabetic) mouse, a model of autoimmune diabetes. There are also similarities in the binding of insulin and other peptides to these two molecules [37]. Recent landmark studies in the NOD mouse show that I-Ag7 binds a diabetes-associated insulin peptide (B9-23) in multiple registers: in the thymus, a register binding is used that results in poor negative selection of these autoreactive T cells [38], while presentation to autoreactive T cells in the periphery may use a different binding register that will trigger autoimmune responses [38]. Of note, insulin is the only islet autoantigen shown to be critical for diabetes development in the NOD mouse [39]; therefore, these studies reveal that the molecular basis of a key disease mechanism is explained by the binding features of the predisposing MHC molecule. Likewise, in humans, the molecular interactions of a pre-proinsulin peptide with the HLA-A2 molecule are weak, resulting in low TCR-peptide-HLA binding affinities. These studies illustrate how the molecular features of predisposing HLA molecules can result in poor presentation of a pre-proinsulin peptide and in enhanced probability that

autoreactive CD8 T cells may escape thymic selection and later become autoreactive [40]. The discovery of target antigens and the definition of key molecular MHC-peptide interactions are critical for developing antigen-specific therapies to selectively delete or regulate autoreactive T cells [41].

Genetic predisposition also impairs peripheral tolerance to islet autoantigens. An immunologically relevant expression of insulin and other peripheral antigens is not limited to the thymus, but it is now well described in peripheral lymphoid tissues as well. Human DCs express insulin and several other TRAs [23,42]; studies in mice demonstrate that insulin expression by AIRE-expressing DCs maintains peripheral tolerance to this critical diabetes autoantigen [43]. Several other cell types have been linked to TRA expression in the periphery [24,44,45]; for example, lymph node stromal cells express many TRAs under AIRE transcriptional control and mediate deletion of autoreactive T cells specific for a model autoantigen in transgenic mice; however, these cells do not express insulin [24]. Thus, the immune system has mechanisms ensuring redundancy and complementarity of peripheral TRA expression, to help maintain peripheral tolerance after the involution of the thymus. It is plausible that the same predisposing genes (HLA, insulin, PTPN22), alternative splicing, and epigenetic mechanisms that impact thymic selection may also impart similar influences on TRA expression in the periphery. In the NOD mouse, insulin gene expression in the pancreatic lymph node (PLN) is lost in relation to proinflammatory changes developing as mice age and progress towards diabetes [46]. These studies link reduced insulin expression to another transcription factor, Deaf1, which is alternatively spliced into a less active form in the PLN of NOD mice; similar findings have been replicated in the pancreatic lymph nodes of patients with T1DM [47]. These observations link inflammation to impaired peripheral tolerance, via effects on TRA expression of a critical islet autoantigen. Then, perhaps, anti-inflammatory therapies may have a role in disease prevention and or treatment if they can help preserve peripheral tolerance mechanisms mediated by the presentation of self-antigens.

Multiple risk loci impair peripheral immune regulation. Non-antigen-specific abnormalities of peripheral tolerance are also involved in the pathogenesis of T1DM [48]. Multiple defects impair the function of patients' regulatory T cells and patients' effector T cells are resistant to suppression by regulatory T cells [49]. There is also an imbalance between Th17 immunity and regulatory T cells both in peripheral blood and the PLN of T1DM patients [50]. Several susceptibility loci promote enhanced immune reactivity and less effective control over T-cell selection, activation, and perhaps differentiation into memory and regulatory phenotypes [12]. The effects of these loci are not antigen- or disease-specific; indeed, these loci confer increased risk for several autoimmune disorders. The effects of a selected few, PTPN22, CTLA-4, and IL2RA are summarized here and illustrated in Figure 29.1. Through its effects on TCR signaling, the PTPN22 locus affects T-cell

function in the periphery, and reports indicate that it also impacts the function of regulatory T cells and B lymphocytes [51,52]. The CTLA-4 (Cytotoxic T lymphocytes- antigen-4; CD152) gene encodes for a protein, expressed by activated CD4 and CD8 T cells, which downregulates T-cell responses. CTLA-4 polymorphisms linked to T1DM are associated with reduced levels of a soluble form of CTLA-4 with a negative impact on regulatory T-cell function [53]. Of note, a recent trial showed that CTLA-4-Ig therapy mitigated loss of insulin secretion in new onset patients, albeit the effect was limited in time [54]. Polymorphic variants of the IL2RA gene (coding for the α chain of the Interleukin-2 receptor, IL-2Rα, or CD25) modulate T1DM risk through effects on several functions, including reduced levels of soluble IL-2 receptor [55], reduced STAT5a signaling in antigen-experienced CD4 T cells, and impaired regulatory T-cell function with decreased expression of the FOXP3 transcription factor [56]. Studies from both NOD mice [57] and other autoimmune diseases indicate that impaired IL-2 signaling compromises T regulatory function. Hence, there is interest in using low dose IL-2 to ameliorate autoimmunity by selectively stimulating regulatory T cells [58]. Overall, imperfect regulation of peripheral tolerance mechanisms, largely but not exclusively through effects on regulatory T cells, plays an important role in T1DM pathogenesis.

Genes and environment: a moving target?

Studies from multiple populations have shown shifts of the typical HLA class II gene associations during the last few decades. Indeed, fewer patients carry the high risk heterozygous HLA-DR/DQ genotype, except among younger children [59–63], in whom the disease is becoming more common [4]. In contrast, more patients now carry moderate risk HLA types and genotypes. Such shifts in HLA associations may be explained by stronger environmental pressures that enhance HLA-mediated genetic predisposition and/or broaden the spectrum of diabetogenic gene–environment interactions. Viruses, and especially enteroviruses, rank at the top of the list of environmental factors that have been linked to T1DM [1].

Several lines of evidence support a role for viruses [64]:

1 diabetes incidence correlates with the seasonality of enterovirus infections;
2 reports of T1DM epidemic bouts;
3 associations of T1DM with immune responses to enterovirus and detection of enteroviral RNA, which correlate with islet autoimmunity and β-cell function [65];
4 reports demonstrate higher T1DM risk in the offspring of mothers with enteroviral infections [66] and, related to this observation, enteroviruses may infect the thymus and alter thymic selection processes in turn favoring autoimmunity [67];
5 the identification of a susceptibility gene controlling innate responses to enterovirus [68]: the IFIH1 gene encodes for the interferon induced with helicase C domain protein 1, which

recognizes enteroviral double-stranded RNA (dsRNA) in infected cells and promotes interferon and NFκB responses, followed by the production of inflammatory cytokines. Experimental data suggest that viral infection may lead to sustained interferon responses and upregulation of HLA class I expression in the presence of predisposing IFIH1 alleles, which would in turn increase the potential to expose self-antigens and trigger autoreactive responses. In contrast, T1DM-protective IFIH1 variants may be associated with reduced responses and decreased likelihood to trigger autoimmunity (Figure 29.1);

6 growing evidence that enterovirus can infect β cells in T1DM patients [69,70]: studies in large cohorts of deceased donors show that the presence of viral antigen is detected much more frequently in the pancreas of T1DM patients compared to patients with T2DM and nondiabetic subjects [70]. Further, enteroviruses can infect and damage β cells, induce expression of HLA class I antigens and alpha-interferon [69], which could amplify inflammation and provide a link to the triggering of islet autoimmunity. Enterovirus infections may also induce functional changes and influence β-cell replication [65,71].

Researchers are testing the hypothesis that multiple, acute viral infections and/or chronic viral infections may repeatedly trigger and sustain autoimmunity over time. Future studies could possibly link one or more serotypes to T1DM, with obvious implications for improved prediction, prevention, and treatment against the triggering and progression of islet autoimmunity.

Multiple T-cell types and autoreactive T-cell specificities mediate T1DM

The inflammatory lesion known as insulitis is considered the pathologic hallmark of T1DM, typically seen during the prediabetic stage or around the time of onset: it consists of the infiltration of the pancreatic islets by lymphocytes and other inflammatory cells. Of great significance is the observation that β cells of NOD mice contain granules enriched in a diabetogenic insulin peptide (B9-23), which is up-taken by intra-islet DCs and presented to CD4 T cells in the PLN [72,73]. This finding calls attention to the β cell itself as the source of a peptide antigen which, at least in the NOD mouse, is the main driver of islet autoimmunity [39]. Once activated in the PLN, autoreactive CD8 T cells recognize MHC class I restricted islet autoantigens directly on the β-cell surface and mediate their cytotoxic effects through multiple effector molecules, including perforin, Fas ligand, and Th1 cytokines, such as IFN-γ and TNF-α. CD4 T cells are linked with the triggering of the autoimmune process and support activation and recruitment of cytotoxic CD8 T cells into the islets. However, CD4 T cells also stimulate β-cell killing via the secretion of cytokines and via signaling through death receptors (Fas, TNF-α) [73]. While T1DM is traditionally considered to be mediated by Th1 type T cells, growing evidence implicates Th17 T cells, which have been shown to have deleterious effects on β cells [74].

In both patients and animal models, studies have identified multiple CD4 and CD8 T cells reacting against a variety of islet autoantigens [2], including multiple epitopes from the autoantigens insulin/proinsulin, GAD65, IA-2, IGRP, and ZnT8. In patients, most studies are limited to peripheral blood samples; however, progress has been made in validating that these cells are linked to disease pathology in the target organ: (1) insulin autoreactive T cells were found in the PLN of T1DM patients [75]; (2) in pancreas transplant recipients, proinsulin/insulin and GAD-specific CD4 T cells were detected in both the circulation and the pancreas transplant lymph node in biopsies in association with recurrent diabetes, as demonstrated by insulitis in the transplanted pancreas [76]. Recent studies also provide functional evidence for the pathogenic role of human autoreactive T cells: (1) GAD-reactive CD4 T cells from the above pancreas transplant patients with recurrent diabetes killed human islets, *in vivo*, when co-transplanted under the kidney capsule of immunodeficient mice [76]; (2) proinsulin-specific CD8 T cells from the peripheral blood of T1DM patients kill β cells *in vitro* [77]; (3) autoreactive T cells were directly demonstrated in the insulitis lesion, in the pancreas of an organ donor with T1DM, using MHC tetramers [78].

Autoimmunity persists in many patients even many years after diagnosis

Studies in patients with long disease duration suggest that β-cell function may persist long after diagnosis [79,80] in a significant proportion of patients. There is also evidence suggesting the co-existence of some low level of regeneration with chronic autoimmunity [81], as islet autoimmunity may also persist or perhaps be reactivated years after diagnosis. Indeed, significant proportions (30–40%) of islet or pancreas transplant recipients express one or more autoantibodies when evaluated prior to transplantation [82]. Moreover, persisting autoreactive T-cell responses detected prior to transplantation correlate with islet graft failure on follow-up [83]. These cells may be expanded following transplantation, since the lymphopenia induced by chronic immunosuppression may promote homeostatic proliferation of memory T cells, which in patients with an autoimmune disease will include autoreactive T cells [84]. The persistence and/or reactivation of islet autoimmune responses is an obstacle to curing diabetes through transplantation, and autoimmunity may not be completely controlled by the immunosuppression used to prevent transplant rejection [76]. Thus, islet autoimmunity may be active for many years, throughout the diabetes clinical spectrum (Figure 29.2), and not just limited to the time prior to and around diagnosis.

Nonautoimmune factors

Additional factors may play a role in the disease pathogenesis, and may promote β-cell dysfunction and progression of islet

The T1DM Spectrum
Figure 29.2 The T1DM clinical spectrum. Illustration of the various clinical stages of the diabetes clinical spectrum and of the biologic phenomena that are the subject of intense research.

autoimmunity. Insulin resistance affects about 20% of young patients with T1DM, especially during puberty. Importantly, insulin resistance precedes T1DM diagnosis and accelerates the progression of islet autoimmunity [85–88]. Obesity and T2DM have become more common in children [89]; children with T1DM are often overweight [89], suggesting that certain pathogenic mechanisms may be shared between T1DM and T2DM [90]. Significant changes in metabolite profiles (amino acids, lipids, fatty acids) precede islet autoimmunity in genetically at-risk children, which could be linked to inflammation and possibly apoptosis occurring in the pancreas [91,92], which has been linked to the PTPN2, a susceptibility gene expressed in islet cells that control apoptosis [93]. Insulin resistance and metabolomic changes may be also be related to inflammation. In the SEARCH study, young patients with T1DM had elevated serum levels of IL-6, fibrinogen, and C-reactive protein [94]; stimulation of patients' monocytes via toll-like receptors is followed by exaggerated IL-6 responses [95]. Of note, IL-6 has been linked to increased Th17 T-cell responses and impaired regulatory T-cell function [96]. The serum of T1DM patients is characterized by a proinflammatory signature that includes

IL-1 and several chemokines [97], many of which were also expressed in the pancreas of T1DM patients [98]. Proinflammatory cytokines have deleterious effects on β-cell function and survival [99], and pancreatic islets from patients with T1DM reportedly express markers of endoplasmic reticulum stress [100]. Inflammation is often associated with obesity, and can be modulated by genetic and environmental factors. In addition to a possible role of enteroviral infections in promoting inflammation in the gut [101], there is growing evidence that dietary habits can influence intestinal permeability and the composition of the gut flora [102]; this in turn can influence production of cytokines, chemokines [98], innate immune responses [95], and the function of gut-associated lymphocytes, including regulatory lymphocytes.

Overall, growing evidence points at inflammation and metabolic changes as significant factors in T1DM pathogenesis. These could even precede the triggering of islet autoimmunity, and may promote chronic immune dysregulation through effects on both innate and adaptive immune responses. Of note, some of the genes linked to T1DM risk include genes that influence the innate immune system [12]. Further genetic studies

may provide a genetic underpinning for these and additional disease pathways, considering that not all of the T1DM risk loci map to immune function genes, that some susceptibility genes are expressed in islet cells, and that additional susceptibility genes remain to be mapped [12].

The relationship between pathogenic factors and β-cell destruction remains poorly understood

Longitudinal studies of newborns and children at genetic risk [5,103,104] and follow-up of at-risk first-degree relatives in natural history studies link the triggering of autoimmunity with the appearance of autoantibodies to one or more islet autoantigens; individuals with multiple autoantibodies have higher risk of diabetes progression [3]. Data from the Diabetes Prevention Trial-Type 1 document a progressive impairment of insulin secretion and glucose metabolism as subjects progressed towards diagnosis [105]. Recent clinical studies have led to increased awareness that stimulated C-peptide responses are only partially reduced in many newly diagnosed patients, to an extent as a function of age [106,107]. A two-year follow-up of new onset patients shows greater C-peptide loss during the first year post diagnosis; importantly, not every patient experienced further loss during this period [108]. At least low levels of C-peptide production may persist for several years in a significant proportion of patients, even decades after diagnosis [79,80]. In parallel, it has been proposed that physical β-cell loss at diagnosis may be also age dependent and, importantly, less severe than previously estimated; a recent meta-analysis estimates the average β-cell loss by age 20 at approximately 40% [109]. The effect of age of onset on residual β-cell mass may reflect age-related differences in the number of β cells, but also the influences on β-cell mass and diabetes progression of body mass index and insulin resistance, which increase as children go through adolescence and puberty. Related to the above, the severity of insulitis from pathology specimens also appears to be a function of age, besides disease duration [110]. Insulitis in the human pancreas is generally not as severe and extensive as observed in NOD mice; even among younger patients with short disease duration, who typically have the most severe insulitis and β-cell loss, only about 30% of insulin-positive islets had a lymphocytic infiltrate [110]. Moreover, recent studies described heterogeneous β-cell loss patterns in pancreas pathology specimens from patients diagnosed in childhood with variable disease duration [111]. While it is not possible to correlate insulin secretion with an assessment of β-cell mass in patients with new onset diabetes, studies in pancreas transplant patients with recurrent diabetes, in whom a pancreas transplant biopsy was obtained, often showed moderate β-cell loss and insulitis despite a frank diabetic state [76]. Collectively, these observations raise the provocative question of whether additional co-factors may be impairing β-cell function at the time of diagnosis.

Conclusions

Both genetic and immunologic studies show that autoimmunity plays a major role in T1DM pathogenesis. The molecular characterization of several autoantigens and disease-associated gene variants has led to the identification of several disease pathways and functional abnormalities that contribute to the immune-mediated component of T1DM pathogenesis, many of which are being targeted in clinical trials. Islet autoimmunity appears to be the dominant effector mechanism. Over time, chronic autoimmunity will lead to the virtually complete loss of pancreatic β cells in many but not all patients, given that C-peptide production is detected in a significant proportion of patients, even decades after diabetes onset. There is growing evidence that additional factors contribute to disease pathogenesis and progression; moreover, re-examination of both literature data and emerging findings suggest the hypothesis that a degree of functional impairment may contribute to diabetes symptoms at diagnosis, at least in some patients. If so, additional pathogenic mechanisms and in turn therapeutic targets may exist at diagnosis. Ultimately, a critical gap in our understanding of the disease pathogenesis stems from our inability to assess pathology in the pancreas in relation to secretory function. This prevents us from fully understanding the relationships among insulin secretion, β-cell mass, disease activity, and relative contributions of various factors to disease pathogenesis and clinical symptoms. Longitudinal assessments of T-cell responses during the prediabetic phase are still quite limited; with recent technical improvements future studies should illustrate the dynamics of T-cell responses, antigen specificity, and functional properties of autoreactive T cells in relation to disease progression. Correlations with biomarkers of β-cell destruction have not yet been possible, as another unmet need is a validated biomarker; the levels of circulating, demethylated insulin gene DNA levels could represent such a biomarker if validated in larger studies [112]. There is also hope that further progress will lead to advanced imaging modalities to noninvasively assess β-cell mass and insulitis [113]. This need is even more critical now that improved knowledge of the disease natural history shows relative preservation of C-peptide secretion at diagnosis and later follow-up in many patients, suggesting that the therapeutic window for intervention may extend beyond the first few months from clinical diagnosis.

Key points

- Type 1 diabetes (T1DM) is a complex disease, with both genetic and environmental factors contributing to overall disease risk.

- To date, over 50 genetic loci have been implicated in T1DM risk by a mixture of candidate gene analysis and genome-wide association studies. In combination, however, these account for only 70% of the heritability of the disease. The remaining 30% has yet to be explained.

- The largest genetic effect is conferred by the HLA gene region on chromosome 6p21. This alone accounts for approximately 40–50% of disease heritability. Disease risk cannot be attributed to a single locus within this region, however. Genetic and functional studies suggest that the majority of HLA-mediated risk is conferred by the *HLA-DRB1*, *−DQA1* and *-DQB1* loci, although alleles at the *-DPB1*, *HLA-A*, *HLA-B*, and other loci also modulate disease susceptibility.

- The greatest risk of T1DM is conferred by the *DRB1*0301.DQA1* 0501.DQB1*0201/DRB1*04. DQA1*0301.DQB1*0302* genotype (termed *DR3.DQ2/DR4.DQ8*), which increases the odds of developing the disease approximately 16-fold. In contrast, strong dominant protection is conferred by *DRB1*1501.DQA1*0102.DQB1*0602* (*DR15.DQ6*). A range of other HLA haplotypes have more moderate effects on disease risk.

- Sequence variants in the insulin gene (*INS*) and *PTPN22* gene increase the risk of T1DM approximately twofold.

- The remaining susceptibility loci have more modest effects on disease risk (modifying risk by 5–30%) and, in the majority of cases, the causal variants remain to be identified.

- Current understanding of the genetic basis of T1DM has provided valuable insights into the mechanisms underlying the loss of T-cell tolerance to β-cell autoantigens and identified promising therapeutic targets for disease prevention.

- Further research is necessary to fully define the genetic background of T1DM. Future association studies of sequence variants should be complemented by functional genomics and mechanistic studies to elucidate the molecular pathways underlying the pathogenesis of T1DM and identify putative disease loci along these pathways.

Introduction

Type 1 diabetes (T1DM) is a chronic autoimmune disease in which the β cells of the islets of Langerhans are selectively destroyed, resulting in insulin deficiency and hyperglycemia. The disease develops in genetically susceptible individuals, most likely as a result of an environmental trigger. T1DM has an uneven geographical distribution; disease prevalence is highest in populations of white European origin and lowest in those of East Asian descent [1]. A marked gradient in disease risk also exists in Europe, with higher prevalence of T1DM in northern countries, particularly Finland, compared with areas around the Mediterranean. This pattern could be attributed to genetic differences between the populations or to the presence/absence of environmental triggers.

The sibling relative risk (λ_s) measures the probability of a disease developing in a sibling of a proband compared with the risk in the general population. This index of familial clustering is often used as a measure of genetic effect, although it could also reflect the impact of shared environmental exposures. The λ_s for T1DM is 15 (sibling risk 6%/population risk 0.4%), one of the highest values observed among common complex diseases, suggesting a substantial inherited component to T1DM [2]. This is further supported by the high concordance rate observed among monozygotic (MZ) twins (>50%), while concordance in dizygotic (DZ) twins is similar to that seen for other siblings (6–10%) [3]. A long-term follow-up study of initially discordant MZ twins showed that 65% of the nonproband co-twins developed T1DM by the age of 60 years, while 78% developed persistent islet autoimmunity, suggesting that genetic susceptibility persists for life [4]. Concordance does not reach unity, however, and there is significant divergence between twins in the time taken to develop disease. This implies that environmental factors are also important. Epidemiologic evidence of a

marked increase in T1DM incidence in many areas of the world over the past 20–30 years [5,6] also supports a significant contribution from environmental risk determinants, as do studies of migrant populations, which suggest that individuals from a low-prevalence country can increase their risk of developing T1DM if they move to an area of higher prevalence [7]. This increase in risk may be attenuated by the individual's genetic background, however, such that they do not acquire as high a disease risk as the indigenous population of their adopted country [8,9]. Conversely, children from high-risk populations who are born and raised in areas with lower T1DM prevalence (such as those of Sardinian ancestry raised in Italy) retain their higher risk of disease compared with the host population, underlining the importance of genetic makeup to T1DM risk [10].

Type 1 diabetes is a polygenic disease, in which a large number of susceptibility loci contribute to overall disease risk. The susceptibility genes have low penetrance and, as a result, not all individuals judged to be "genetically at-risk" will develop the disease. Furthermore, diabetes can occur in the absence of known high-risk markers. The lack of a simple relationship between genotype and phenotype makes it difficult to identify disease genes at a population level and studies rely on the detection of statistical associations that are unlikely to have occurred by chance. To date over 50 genetic loci have been shown to be reproducibly associated with T1DM [11, http://t1dbase.org]. In most of these regions, however, fine-mapping is required to define the specific gene(s) involved and identify the causal variants. This chapter reviews our current understanding of the genetic basis of the disease and discusses the implications for disease prediction and the identification of novel targets for intervention in the development and progression of islet autoimmunity.

The HLA complex

The genes of the human leukocyte antigen (HLA) complex were first identified as important determinants of T1DM risk in the 1970s [12]. Subsequent family studies comparing disease concordance rates between HLA-identical siblings and monozygotic twins suggested that the HLA genes are the major genetic contributor to T1DM, accounting for about half of the familial aggregation of the disease [13]. Recent studies concur with this estimate and no other locus with such a substantial influence on disease risk has been identified [2,11].

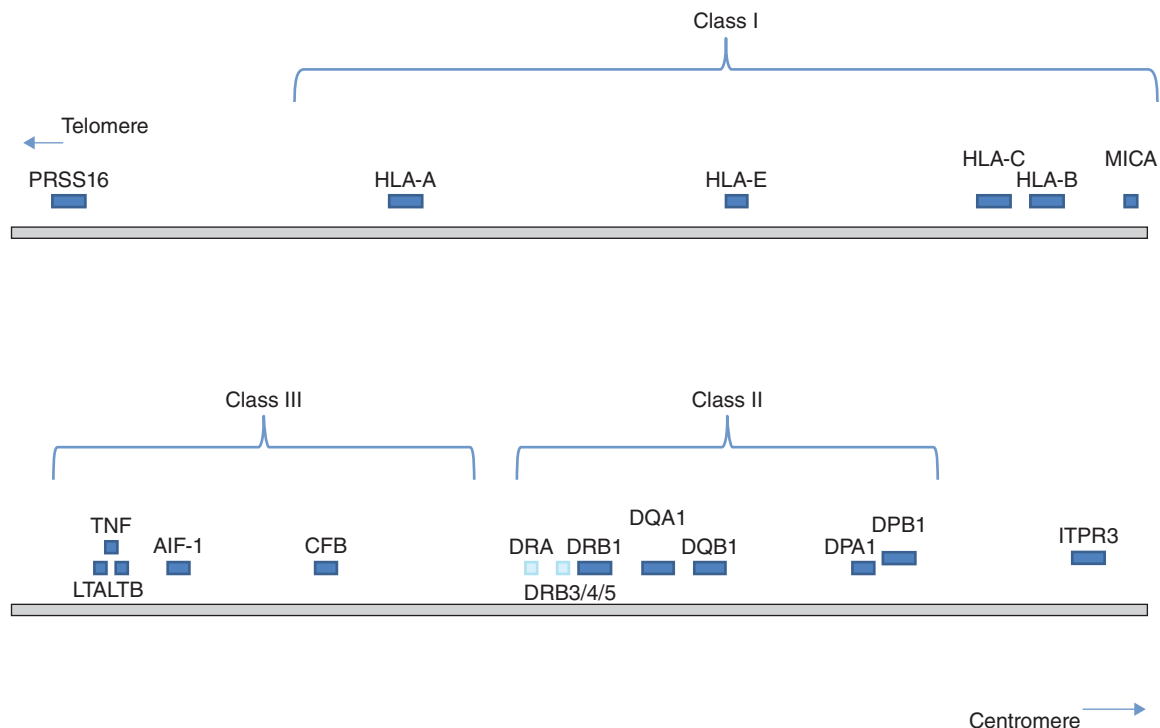
The HLA complex (also known as the human major histocompatibility complex, MHC) maps to a 3.6 Mb region on chromosome 6p21.31 and consists of more than 200 identified genes, over half of which are known to be expressed. The HLA class I genes are located at the telomeric end of the complex, with the class II genes at the centromeric end. The 700 kb sequence between these gene clusters is commonly referred to


Figure 30.1 A simplified map of the human major histocompatibility complex (MHC) on chromosome 6p21.31. The genes reported to be reproducibly associated with T1DM in several independent datasets are shown in dark gray.

as the HLA "class III" region, although it contains no classical HLA genes (Figure 30.1). The HLA complex plays a crucial role in the immune response, in particular the genes encoding the classical class I (HLA-A, -B, and -C) and class II (HLA-DR, -DQ, and -DP) molecules. The *HLA-A*, *-B*, and *-C* genes each encode a peptide chain that combines with β2 microglobulin to form the HLA class I molecules, expressed on the surface of all nucleated cells (Figure 30.2(a)). These molecules bind to peptides derived from exogenous antigens and present them for recognition by CD8-positive cytotoxic T cells. The class II loci are composed of pairs of genes, an A gene and a B gene, which encode an α and β peptide chain, respectively. These dimerize to form the HLA class II molecules, which are expressed only on the surface of specialized antigen-presenting cells, including monocytes, macrophages, and dendritic cells (Figure 30.2(b)).

The DR, DQ, and DP molecules bind to peptides derived from endogenous antigens and present them for recognition by CD4-positive helper T cells (Figure 30.3). The process of antigen presentation is the first step in the activation of a T cell-mediated immune response to the antigen and the HLA molecules therefore play a crucial role in both protection from pathogens and the development of autoimmunity.

The HLA genes are highly polymorphic, some having more than 200 known alleles. This sequence diversity is driven by a strong selective pressure that ensures the recognition of a wide range of antigens to optimize the immune response to a large variety of current and emerging pathogens. As such, the majority of the sequence polymorphism occurs in the gene regions encoding the peptide binding groove. The resulting polymorphic amino acid residues influence the shape and chemical
Figure 30.2 A schematic representation of HLA class I and class II molecules expressed on the cell surface. (a) Class I molecules are composed of an α peptide chain (encoded by an HLA class I gene) and β2 microglobulin (β2m). (b) Class II molecules are heterodimers formed from one α and one β chain, each encoded by a class II locus. Peptides bound in the antigen-binding grooves are denoted by black triangles.
Figure 30.3 A diagrammatic representation of antigen presentation and T-cell activation showing the function of the T1DM-associated loci (*HLA*, *CTLA4*, *PTPN22* (encodes LYP) and *IL2RA* (encodes CD25)). The arrows illustrate the effect of CTLA4, LYP, and IL2R on T-cell activation;↑ promotes T-cell activity, ↓inhibits T-cell activity. TCR, T-cell receptor.

properties of the groove and thereby dictate the repertoire of peptides that can be presented by a given HLA molecule.

Early studies of the HLA gene complex identified disease associations with alleles at individual loci. These genes are in strong linkage disequilibrium (LD), however, which means that recombination between different HLA loci is rare. As a result, combinations of alleles at different genes are inherited together more frequently than expected by chance. When inherited on the same chromosome, this allelic combination is known as a haplotype. For example, the *DRB1*0301* allele is most frequently coinherited with *DQA1*0501* and *DQB1*0201*, forming the *DRB1*0301-DQA1*0501-DQB1*0201* haplotype. Haplotypes can only be determined directly in family studies, where transmission of allele combinations from parent to child can be recorded. Strong LD relationships between alleles, however, make it possible to assign haplotypes based on the likelihood of allele co-occurrence, using computer algorithms. Unfortunately such relationships also make it difficult to determine which loci make a genuine contribution to disease risk and which are associated with disease secondary to their coinheritance with other disease markers.

The major HLA-encoded susceptibility determinants for T1DM are the class II DR and DQ genes, although the DP genes and the class I genes also influence disease risk. The effect of a given allele/genotype on the risk of developing disease is generally indicated by the odds ratio (OR), which compares the frequency of the disease occurring in individuals positive for the genetic variant with the frequency in individuals lacking the

variant. An OR of 1 indicates that the allele/genotype has no influence on disease risk; typically, an OR value greater than 1 suggests that the marker confers susceptibility to the disease, while markers with OR values less than 1 confer protection.

HLA-DR and *-DQ*

The highest risk of T1DM is conferred by heterozygosity for the *DRB1*0301-DQA1*0501-DQB1*0201* and *DRB1*04-DQA1*0301-DQB1*0302* haplotypes, referred to as the *DR3.DQ2/DR4.DQ8* genotype. This allelic combination is carried by 30–40% of individuals with T1DM, but only around 2.5% of the general population [3]. A recent meta-analysis of multiple ethnic groups suggested that this translates into an OR value greater than 16, an unusually large odds ratio for a complex disease [14]. This is consistent with an earlier study which estimated that the risk of developing T1DM was between 1 in 15 and 1 in 25 among those with the *DR3.DQ2/DR4.DQ8* genotype, compared with 1 in 300 in the general population [15]. High risk is also conferred by the *DR3.DQ2/DR3.DQ2* and *DR4.DQ8/DR4.DQ8* homozygous genotypes (OR = 6.32 and OR = 5.68, respectively, from meta-analysis) [14]. Approximately 95% of subjects with T1DM are positive for *DR3.DQ2* and/or *DR4.DQ8* compared with 40–50% of the general population [3]. It is noteworthy that heterozygosity for these haplotypes confers a much greater risk than would be expected from the combined OR values observed for each homozygous genotype, suggesting that the alleles on each haplotype interact synergistically to promote disease development. This may be due to the formation of a highly

diabetogenic DQ molecule, encoded *in trans* by *DQA1*0501* on the DR3 haplotype and *DQB1*0302* on the DR4 haplotype. This potential synergism supports the conclusion that the HLA genotype of an individual (the combination of alleles inherited from both parents) is a better indicator of disease risk than the presence or absence of specific risk alleles.

Although the *DR3.DQ2* and *DR4.DQ8* haplotypes are the strongest determinants of T1DM risk, there is a complex hierarchy of allelic, haplotypic, and genotypic effects of the DR/DQ loci, which encompass the spectrum from highly susceptible, through intermediate risk, to very protective markers. The haplotypes most strongly associated with T1DM (predisposing and protective) are summarized in Table 30.1. As shown, the risk conferred by *DRB1*04* haplotypes varies considerably according to the specific *DRB1* allele present. *DRB1*0405* and **0401* are associated with the highest risk, while *DRB1*0403* confers protection against T1DM [16]. Indeed the protective influence of *DRB1*0403* is able to override *DQA1*0301-DQB1*0302*-associated susceptibility, even among individuals carrying the high risk *DR3.DQ2/DR4.DQ8* genotype [17]. The *DRB1*1501-DQA1*0102-DQB1*0602* (*DR15.DQ6*) haplotype is particularly interesting as it confers strong protection against T1DM, occurring in less than 1% of individuals with the disease compared with 20% of the general white European population. The protective effect is dominant over susceptibility conferred by other alleles; individuals carrying the *DR15.DQ6* haplotype in combination with the predisposing *DR3.DQ2* or *DR4.DQ8* haplotype do not usually develop diabetes [18]. The analysis of the transmission of DR/DQ alleles from unaffected parents to diabetic offspring suggests that protection is likely to be conferred by *DQ6* (*DQA1*0102-DQB1*0602*) rather than *DRB1*1501*. Rare haplotypes carrying *DRB1*1501* in the absence of *DQ6* are transmitted significantly more frequently than the *DQ6* allelic combination alone [19]. *DQ6* can prevent progression to overt T1DM even after the onset of islet autoimmunity, suggesting that the molecule encoded by these alleles may have an immunomodulatory role [20]. The protective effect is not absolute, however, as a small number of individuals with T1DM have been shown to be positive for *DQA1*0102-DQB1*0602* [21,22]. It is possible that protection from disease is attenuated in these subjects by the effects of other loci [23–25]. Other DR/DQ haplotypes also exert strong protection from T1DM (Table 30.1), but are much less common in the background population than *DR15.DQ6*.

It is difficult to dissect the relative contributions of the DR and DQ genes to disease susceptibility using purely genetic means as the tight LD between the loci hampers attempts to dissociate the effect of a given allele from the effects of other alleles with which it is coinherited. Studies of HLA-transgenic animals, however, have suggested that both DR and DQ molecules play a role in the pathogenesis of T1DM. B10 mice expressing human DR3 (*DRB1*03*) or DQ8 (*DQA1*0301-DQB1*0302*), singly or in combination, developed spontaneous T-cell reactivity to glutamic acid decarboxylase (GAD65), a β-cell protein implicated

Table 30.1 An illustration of the hierarchy of HLA-DR/DQ haplotypes, showing those most strongly associated with T1DM risk. OR (odds ratio) values are quoted for white Europeans [64], except those marked * which are quoted for Japanese [65]

in the autoimmune disease process, while insulitis occurred in DR3/DQ8 double transgenic animals [26,27]. Expression of DQ8 or DR4 (*DRB1*0401*) in C57BL/6 mice was unable to induce insulitis, but when these animals were crossed with transgenic mice expressing the T cell co-stimulatory molecule, B7.1, on their pancreatic β cells, the resulting double transgenic offspring developed spontaneous diabetes [28,29]. Similarly, the coexpression of B7.1 was necessary for diabetes to develop in mice transgenic for DR3 and/or DQ8 [30]. Interestingly, in this study, the DR3 and DQ8 molecules appeared to be equally permissive for islet autoimmunity. In contrast, Kudva and coworkers reported greater insulitis in the presence of DQ8 alone, with the coexpression of DR3 apparently decreasing the frequency and severity of autoreactivity in double transgenic animals [31]. A similar observation was made in DR4/DQ8 transgenic mice; DQ8 appeared to be the more diabetogenic molecule, with its effect being downregulated by the coexpression of DR4 [29]. These studies suggest a primary role for DQ in the development of autoimmunity, with DR playing a regulatory role. Significantly, transgenic mice expressing the DQ6 molecule did not develop autoimmunity to GAD65, even in the presence of DR3 or DQ8 [26]; this is consistent with the dominant protective effect reported for DQ6.

The influence of a particular HLA molecule on diabetes risk is largely determined by its three-dimensional structure, which governs the way in which it interacts with autoantigenic peptides and the receptors of autoreactive T cells.

The antigen-binding sites of diabetogenic molecules, such as DQ2, DQ8, and I-A^{g7} (the diabetes-predisposing MHC molecule found in nonobese diabetic [NOD] mice), share similar chemical and geometric properties that dictate the shape of the critical pockets into which the amino acid side chains of antigen peptides are anchored during presentation. Likewise there is marked structural similarity between the diabetes-protective molecules, such as DQ6, DR4 (*DRB1*0403*), and murine I-A^{b} [32]. The structural features differ markedly between the two groups, however, leading to differences in antigen selectivity, binding affinity, and molecular stability. It is unclear how this translates into effects on disease risk, but it has been hypothesized that diabetogenic molecules may bind poorly to autoantigenic epitopes, leading to ineffective tolerance induction and subsequent autoimmunity. In contrast, the protective molecules bind well to self antigens, promoting efficient thymic deletion of autoreactive T cells. The potential "loss of function" mechanism for the predisposing molecules is supported by the observation that transgenic overexpression of the diabetogenic allele, I-A^{g7}, in NOD mice protects from diabetes, presumably by compensating for the low affinity of the encoded molecule for autoantigens [33].

Other HLA-encoded susceptibility determinants

The DR and DQ genes cannot completely explain the association between T1DM and the HLA gene region. Teasing out the contribution of other HLA loci, however, is complicated by the high level of linkage disequilibrium within the region, combined with the strong effects of DR and DQ. A number of different approaches have been employed to address this issue, including the analysis of case/control data matched for specific DR-DQ combinations, investigation of the transmission to affected and unaffected offspring of heterozygous markers from parents homozygous for DR-DQ alleles, conditional logistic regression and conditional haplotype analysis. These, and other methods, have identified additional disease risk markers at the *HLA-A*, *-B*, *-C*, and *-DPB1* loci, in the "class III" gene region and in loci located telomeric and centromeric of the classical HLA gene region (see Figure 30.1).

A number of association studies have implicated variants of the *DPB1* gene in T1DM risk, but results are conflicting between datasets. A recent analysis of high-resolution genotyping data in a large family-based cohort from the Type 1 Diabetes Genetics Consortium (T1DGC) showed that disease risk was increased by *DPB1*0202* and *DPB1*0301*, while *DPB1*0402* conferred protection from diabetes [34]. These associations remained significant after relative predispositional analysis, adjusting for the effects of LD with the DR-DQ loci. The *DPB1*0301* allele was found to increase disease risk both in the presence and absence of high-risk susceptibility DR-DQ alleles. In contrast the predisposing effect of *DPB1*0202* was seen only in individuals carrying the high-risk and protective DR-DQ haplotypes, while *DPB1*0402* conferred protection only in the absence of the high-risk and protective DR-DQ haplotypes.

Similar conditional analyses in the T1DGC dataset have identified HLA class I alleles that influence the risk of diabetes independently of DR and DQ [35,36]. The most significant disease associations reported by Noble and coworkers [35] were with *HLA-B*5701* (protective) and *B*3906* (predisposing). Increased disease risk was also conferred by *A*0201*, *A*2402*, *B*1801*, and *C*0501*, while *A*1101*, *A*3201*, *A*6601*, *B*0702*, *B*3502*, *B*4403*, *C*0401*, and *C*1601* were all associated with protection. The predisposing effects of HLA-*A*24*, *B*39*, and *B*18* and reduced disease risk conferred by *A*11* were confirmed by Howson et al. [36]. In addition, *HLA-B*13* and *B*50* were found to increase T1DM risk independently of DR and DQ, while *A*01* conferred protection. It has been postulated that HLA class II molecules play an important role in the initiation of the autoimmune response in T1DM, while class I molecules mediate the later stages of β-cell destruction.

A number of other loci in the MHC have been reported to influence the risk of T1DM independently of DR and DQ, including the *TNFA*, *AIF1*, *PRSS16*, and *ITPR3* genes (Figure 30.1), although the association with the latter marker could not be confirmed in an independent study and may be secondary to the effect of *DQB1* [14]. Single nucleotide polymorphisms (SNPs) mapping close to *LTA* and *CFB* have also been associated with disease on DR3 and DR4 haplotypes.

Overall HLA genes contribute to 40–50% of the genetic risk of T1DM, with the strongest effect seen in individuals developing the disease at an early age. As the incidence of T1DM has risen over past decades, however, a temporal change has been observed in the impact of specific genotypes on disease risk [37]. The proportion of patients with high-risk HLA genotypes has decreased, suggesting that greater environmental pressure is boosting disease penetrance in subjects with moderate- and low-risk HLA genotypes.

Other candidate genes for T1DM

The candidate gene approach has been used to identify a number of T1DM risk loci outside the HLA gene region. This method seeks disease associations with sequence variants at loci thought to play a biologic role in disease etiology. The insulin gene and immune response genes are the most logical candidates for T1DM and a large number of polymorphisms have been reported to be associated with disease risk over the last 30 years. Many of these have proved to be false positive results, artefacts caused by limited sample sizes and population stratification. Some, however, have been replicated in independent datasets and have functional data to support their role in disease etiology. These validated loci are described in the following sections and the role of the immune response genes in T-cell activation is illustrated in Figure 30.3.

The insulin gene (*INS*)
Outside the HLA locus, the strongest signal for T1DM risk maps within and upstream of the *INS* gene on chromosome

11p15.5 (OR ~ 2.0). It is unclear whether the etiologic variant is a variable number of tandem repeats (VNTR), located approximately 0.5 kb upstream of *INS*, or two noncoding SNPs that are in complete LD with the VNTR [38]. Homozygosity for class I VNTR alleles (26–63 repeats) is associated with an increased risk of T1DM, while class III alleles (140–210 repeats) are generally dominantly protective. These markers appear to exert their influence by modulating insulin gene transcription in the thymus. *INS* expression from class I alleles is more than twofold lower compared with that driven by class III alleles [39]. The resulting low level of insulin in the developing thymus of class I homozygotes is thought to lead to autoimmunity by impairing the deletion of insulin-specific T cells. In contrast, the higher level of insulin present in class III allele carriers promotes T-cell tolerance to the autoantigen and protects against T1DM. In support of this hypothesis, rare class III alleles that completely repress thymic insulin expression confer an increased risk of diabetes [40].

The *CTLA4* gene

The *CTLA4* gene on chromosome 2q33.2 encodes a transmembrane co-receptor expressed on the surface of T cells. This functions as a negative regulator of T-cell activation via interaction with the B7 molecule on antigen-presenting cells (Figure 30.3). The G allele of the +49A/G SNP in exon 1 of *CTLA4* has been implicated as a susceptibility marker for T1DM, but was rejected as a causal SNP by a fine-mapping study, which showed that its effect could be explained by more strongly associated variants in a 6.1 kb noncoding region, 3′ of the gene [41]. These polymorphisms were also associated with susceptibility to Graves' disease and autoimmune hypothyroidism, suggesting that *CTLA4* is a general autoimmunity risk locus. The associated variants were suggested to reduce the production of a secreted, soluble form of CTLA4, which is able to inhibit T-cell proliferation by binding to B7 [41]. This was not replicated in a subsequent study, however, and there is doubt as to whether the 3′ SNPs are directly causal for T1DM [42,43].

The *PTPN22* gene

The *PTPN22* gene, located on chromosome 1p13, encodes the lymphoid-specific tyrosine phosphatase, LYP. This enzyme dephosphorylates key molecules in the T-cell receptor signaling pathway and hence functions as a negative regulator of T-cell activation (Figure 30.3). Susceptibility to T1DM (and a range of other autoimmune diseases) is associated with the T allele at the nonsynonymous C1858T SNP of *PTPN22* (OR = 1.96) [44]. This polymorphism results in an arginine-tryptophan substitution at position 620, an amino acid residue that plays a critical role in the interaction of LYP with its inhibitor, SRC kinase. The gain-of-function polymorphism results in a phosphatase with increased catalytic activity, which is a more potent negative regulator of T-cell activation [45]. This is thought to interfere with the induction of immune tolerance in the thymus or periphery, hence predisposing to autoimmunity.

The *IL2RA* gene

The interleukin-2 (IL-2) receptor α chain (CD25), encoded by the *IL2RA* gene on chromosome 10p15, is upregulated in activated effector T cells but constitutively expressed by FOXP3-positive regulatory T cells, which are known to play an important role in self-tolerance. The α subunit greatly enhances the affinity of the IL-2 receptor for its ligand and signaling through IL-2R is crucial for the function of both effector and regulatory T cells (Figure 30.3). Risk of T1DM is associated with three independent haplotypes, spanning a region from 18 kb immediately 5′ of *IL2RA* to 25 kb into intron 1 of the gene [46–48]. Disease-associated alleles/haplotypes have been shown to influence levels of soluble IL2Rα in peripheral blood [47], while a protective haplotype, defined by the rs12722495G allele, correlated with higher expression of CD25 on CD4-positive memory T cells and increased IL-2 responsiveness by these cells [48]. The susceptible haplotype, defined by the A allele of this SNP, was associated with reduced IL-2 responsiveness, decreased expression of FOXP3 by regulatory T cells and a reduction in the ability of Tregs to suppress the proliferation of autologous effector cells [49]. Like *CTLA4* and *PTPN22*, the *IL2RA* gene appears to be a general autoimmunity locus, with reports of associations in rheumatoid arthritis, multiple sclerosis, and Crohn's disease.

Genome-wide analyses

Over the last 20 years, advances in high-throughput genotyping techniques and improved understanding of genetic variation in human DNA have enabled researchers to screen the entire genome to identify disease susceptibility loci. Two main approaches have been used: linkage studies and genome-wide association studies.

Linkage studies

Linkage studies identify regions of the genome that are shared more frequently than would be expected by chance by relatives affected by a particular disease. Most studies analyze affected sibling pairs and utilize genetic markers that are scattered throughout the genome at moderate density, typically microsatellites. A significant excess of allele sharing identical-by-descent (IBD) in affected sibpairs suggests that the region containing the marker locus also contains a disease susceptibility locus. The first linkage scan for T1DM identified 20 chromosomal regions with suggestive evidence of linkage to disease, including the *HLA* and *INS* gene regions [2]. Subsequent studies have replicated the linkage with *HLA*, but findings at other loci have been inconsistent. A recent analysis of 2496 multiplex families from the Type 1 Diabetes Genetics Consortium reported significant evidence of linkage to *HLA*, along with a second locus on chromosome 6q. Suggestive evidence of linkage was observed near the *CTLA4* and *INS* genes, along with two regions on chromosome 19 [50].

Genome-wide association studies (GWAS)

One of the limitations of linkage studies is their inadequate statistical power to detect risk variants with small effect sizes. As our understanding of the genetic basis of complex diseases has grown, it has become apparent that many susceptibility genes have a very modest influence on disease risk (OR ≤ 1.3). Such small effects can be detected more readily by GWAS, provided that the alleles at the risk loci are relatively common in the studied population (minor allele frequency >5%) and sufficiently large datasets are available for analysis. GWAS utilize high-throughput genotyping platforms to analyze several hundred thousand single nucleotide polymorphisms (SNPs), providing much denser coverage of the genome than linkage studies. The analysis relies on the assumption that the SNPs selected for genotyping will "tag" potentially causal variants as a result of linkage disequilibrium. The marker SNPs are genotyped in a discovery cohort of affected (cases) and unaffected, unrelated individuals (controls) and those showing suggestive evidence of association with disease are then taken forward for replication in an independent case/control dataset. Due to the large number of SNPs investigated, very large sample cohorts are required in the replication phase to achieve genome-wide statistical significance for a given variant (widely accepted as a p value less than 5×10^{-8}). GWAS are therefore generally performed by international collaborative efforts and large consortia, such as the Wellcome Trust Case–control Consortium (WTCCC) and the T1DGC.

Preliminary analysis of 6500 nonsynonymous SNPs in 2029 T1DM cases and 1755 control samples identified a significant disease association with the minor allele of rs1990760

in the *IFIH1* gene [51]. This locus encodes interferon-induced helicase C domain 1, which serves as a cellular receptor for double-stranded viral RNA and triggers the production of interferon in response to viral infection. As enteroviruses have been implicated as environmental triggers of T1DM development, the *IFIH1* gene may be involved in mediating this effect by activating the innate immune system. The presence or absence of inflammatory signals produced by this system will determine whether T-cell activation in the periphery results in an aggressive effector response or a protective regulatory response.

The first complete GWAS for T1DM was reported by the WTCCC in 2007 [52]. This confirmed associations at known loci (*HLA*, *INS*, *CTLA4*, *PTPN22*, *IL2RA*, and *IFIH1*) and also identified several novel associations with variants on chromosomes 12q24, 12q13, 16p13, 12p13, 5q31, and 4q27. Follow-up studies in different cohorts and meta-analyses of multiple datasets have subsequently confirmed associations at all these loci except 5q31, as well as identifying a large number of additional association signals [11,53]. To date, more than 50 loci have been implicated as determinants of T1DM risk using the GWAS approach; a complete list can be found on the T1DBase website (http://t1dbase.org). Many of these loci are also associated with other autoimmune diseases, suggesting common underlying mechanisms in disease development. The majority of the T1DM risk variants have very small effect sizes, with odds ratios between 1.05 and 1.3, significantly lower than those reported for the HLA genes, *INS* and *PTPN22* (Figure 30.4). Given the statistical power of the GWAS and the large number of SNPs genotyped, however, it is highly unlikely
Figure 30.4 Odds ratios (OR) of more than 40 T1DM susceptibility loci, identified by candidate gene studies (loci marked *) or genome-wide association studies (data from [53] and [66]). The *IFIH1* locus was identified by the analysis of 6500 nonsynonymous SNPs.

that any additional common variants with large effects on disease risk were missed.

It is important to note that, like linkage analyses, GWAS do not directly identify causal variants. The designations often applied to associated variants can therefore be misleading. For convenience, signal SNPs are generally assigned the name of the closest gene, or the most plausible candidate gene in close proximity, as a reference point for their location, although some associated variants map to apparent gene deserts, with no known annotated genes. Close physical proximity of a candidate gene, however, does not necessarily mean that the gene has any functional involvement in disease pathogenesis or that it accounts for the risk associated with the nearby variant. Many disease associated variants map to large blocks of LD, which may span hundreds of kilobases and encompass many genes. In most cases the signal SNP will merely be a marker for a causal variant located somewhere in the LD block. Fine mapping is therefore required to narrow down the likely location of this etiologic SNP. This is generally achieved by deep sequencing of the LD region of interest to identify all the polymorphisms that might contribute to the observed association. These are then genotyped in large case–control cohorts and conditional regression analysis is used to tease out the contribution of each variant and determine whether this can be explained by LD with other SNPs or is an independent phenomenon. This approach often narrows down disease association to haplotypes comprising many closely correlated variants, but further refinement cannot be achieved using genetic means due to very strong LD between the SNPs. Functional analysis is then necessary to home in on the causal variant(s). This may be accomplished by identifying polymorphisms known to influence gene expression levels (from publicly available expression QTL (eQTL) databases) or missense variants within the associated haplotype that could disrupt protein function.

The T1DM risk loci identified by GWAS contain over 300 protein-encoding genes, many of which are good candidate genes due to the role of their products in immunologic or metabolic pathways. This estimate excludes genes located outside the associated LD blocks that could have regulatory elements within the blocks. As functional SNPs may exert their effects via long-distance gene regulation, their contribution to disease risk may be mediated by genes located several kilobases away from the LD blocks in which the SNPs lie. This highlights the difficulties involved in conclusively identifying the causal gene variants and elucidating the genetic mechanisms underlying T1DM risk. To date, only the *HLA* gene region, *INS* and *IL2RA* have been fine-mapped with any degree of thoroughness, although functional studies also support the *PTPN22* R620W variant as a causal SNP.

To date, GWAS for T1DM have been performed exclusively in white European datasets, due to the difficulty in recruiting sufficiently large cohorts from other ethnic groups, in which the disease is relatively rare. One drawback of this limited approach is that some susceptibility loci might have been overlooked if their minor alleles occur with low frequency (<5%) in white

Europeans, as the studies would have been underpowered to detect the associations. Allele frequencies at some loci are increased in certain populations as a result of population genetic drift, thus boosting statistical power to detect disease associations with these variants. It is therefore possible that additional susceptibility loci for T1DM may be discovered if different ethnic groups are analyzed by GWAS. A second issue is that it is not known whether the T1DM risk loci identified in white Europeans have global relevance. To date, studies have not attempted to replicate associations at all the GWAS loci in non-White populations as available datasets are too small. Candidate gene studies have shown suggestive evidence of population-specific effects, however. For example, the M55V variant of the *SUMO4* gene is strongly and consistently associated with T1DM in East Asian populations, but not in white Europeans [53,54]. In contrast, the disease association with the R620W variant of *PTPN22*, reported in white Europeans, is not seen in Asians [55], perhaps due to the rarity of the minor allele in the latter population. Genetic heterogeneity between different populations is perhaps to be expected, given that most of the genes influencing T1DM risk are likely to act via the immune system. Population survival is dependent upon the adaptation of the immune response to local environmental insults, which are likely to differ in different areas of the world. This shaping of the immune repertoire might be reflected in ethnic differences in immune response genes. As a result, it may not be possible to extrapolate all genetic associations observed in European populations to populations of different racial ancestry. There is clearly a need to broaden genome-wide analyses to encompass a more diverse set of populations of different ethnic ancestry to fully understand the contribution of genetic factors to disease risk on a global scale. Exploitation of differences in LD patterns in different ethnic groups may also facilitate the fine-mapping of causal variants for T1DM.

Other genetic markers—the "missing heritability"

Collectively the confirmed T1DM risk loci account for approximately 70% of disease heritability, with around 40–50% being attributed to the *HLA* genes. These figures are well in excess of the 10–20% of heritability of other complex diseases that can be explained by genetic factors. Experience from GWAS suggests that overall disease risk is likely to be influenced by many genes, most having a weak biologic effect. This may be due to the subtle effects of risk alleles on gene function or the modest contribution of individual gene products to the biologic pathways involved in disease pathogenesis. None of the confirmed T1DM risk variants have complete penetrance and are therefore neither necessary nor sufficient for disease to develop. This makes it difficult to use genetic profiling to predict disease risk as T1DM can develop in the absence of susceptibility variants and does not always occur in subjects with known risk markers. Furthermore the combination of susceptibility variants underlying T1DM

may differ between populations or between individuals according to their exposure to different environmental triggers. Further GWAS efforts with ever-increasing sample sizes may discover additional common risk SNPs, but their effect sizes are likely to be similar to, or smaller than, those already identified and they are unlikely to explain the missing 30% of heritability.

Recently, interest has grown in the contribution to T1DM of highly penetrant, low-frequency variants, as these may be expected to cause severe immune dysregulation in the small percentage of individuals who carry them and may therefore account for the missing genetic risk. It is possible that the end-point of autoimmune β-cell destruction could result from a multitude of different immune dysregulation mechanisms, each related to the effects of different rare genetic variants. These loci could therefore be of crucial importance in a substantial proportion of T1DM cases. Such variants are too infrequent to be identified by GWAS, but can be picked up by extensive resequencing of candidate genes. This approach has identified four rare variants in the *IFIH1* gene that independently lower the risk of T1DM and are more strongly associated with disease than the common polymorphisms identified by GWAS [56]. All four variants were predicted to alter the expression and structure of the encoded protein and two (a nonsense mutation in exon 10 (E627X) and a nonsynonymous mutation in exon 13 (Ile923Val)) were subsequently shown to influence the production of inflammatory cytokines in peripheral blood cells [57]. Whole-exome and whole-genome sequencing strategies are now being used to identify other rare variants that influence disease risk.

The inability of existing genetic approaches to directly identify causal variants, combined with the genetic and phenotypic heterogeneity of T1DM, makes it unlikely that the whole spectrum of disease susceptibility variants can be identified by examining statistical associations with sequence variants. Functional genomics and mechanistic studies are required to elucidate important pathogenic pathways, identify disease loci relevant to these pathways and determine genotype-phenotype correlations. Transcriptomic analysis of lymphoid tissue and pancreatic islets can be used to identify genes that are differentially expressed in different states of immune activation, allowing pathogenically relevant gene networks to be determined. These can then be screened for genetic variants that influence specific molecular subphenotypes. Further work is also needed to understand the mechanisms underlying the regulation of susceptibility gene function. The impact of epigenetic modification should also be explored further as this will integrate the influence of environmental factors on disease risk.

Clinical utility of T1DM susceptibility genes

One of the goals of genetic studies of complex disease is to identify a profile of susceptibility variants that can be used to predict an individual's risk of developing a given disease. The long prodrome for T1DM, characterized by progressive loss of β-cell mass, provides an attractive opportunity for intervention to prevent disease development if "at-risk" individuals can be identified. Currently the best markers of disease risk are a positive family history of T1DM and the presence of autoantibodies to islet cell proteins. Over 90% of T1DM patients have no affected relatives, however, so effective preventive efforts will need to target the general population. Unfortunately screening such huge numbers of individuals for islet autoantibodies is logistically unfeasible, particularly given the need for repeated annual testing for those with a negative result. Genetic markers are therefore needed to stratify risk in the general population, to significantly decrease the target population for immunologic screening while still capturing the majority of future cases of T1DM. HLA class II genes have been widely used in research studies to identify high-risk individuals (see later), but testing for HLA alleles alone lacks specificity, sensitivity, and positive predictive value, limiting its use in disease prediction at a population level. Incorporating genotype data for susceptibility SNPs outside the MHC improves prediction slightly but it has been suggested that even if all risk loci were discovered and included in the prediction model, the achievable predictive power might still be inadequate to reliably select individuals from the general population for targeted intervention [58].

Although the HLA genes may have limited utility in large-scale population screening for disease prevention, they are useful markers for stratifying disease risk in research studies. Birth cohorts examining the natural history of T1DM and the impact of environmental determinants on disease development, such as Diabetes Autoimmunity Study in the Young (DAISY), BABYDIAB, and The Environmental Determinants of Diabetes in the Young (TEDDY), use HLA typing to identify newborns in the general population with high and moderate genetic risk of disease and to stratify risk in children with a family history of T1DM [15,59,60]. High genetic risk is defined by the *DR3.DQ2/DR4.DQ8* genotype, while moderate risk is conferred by genotypes carrying one of these high risk haplotypes, in the absence of *DR15.DQ6*. Children positive for *DR3.DQ2/DR4.DQ8* have a 5% risk of developing T1DM by the age of 15 years [14]. If they also have an HLA-identical sibling with T1DM, the risk is even higher; a 65% risk of developing islet autoimmunity by the age of 7 years and a 55% risk of developing T1DM by the age of 12 years [61]. In contrast, the presence of the highly protective *DR15.DQ6* haplotype markedly reduces disease risk, even among individuals with a family history of disease and evidence of islet autoimmunity [20]. HLA genes are also valuable tools for selecting high-risk individuals for trials of novel preventive strategies for T1DM, such as the PrePOINT trial of autoantigen vaccination with oral insulin (http://www.diabetes-point.org) and the TRIGR study of dietary intervention in infancy (http://trigr.epi.usf.edu).

One of the major benefits of the genetic studies of T1DM is the improved understanding of the immune dysregulation underlying the disease. Both innate and T cell-mediated adaptive immunity are implicated by genetic association studies and functional analyses of disease susceptibility variants suggest

that impairment of autoantigen-driven TCR signaling and inefficient negative selection of autoreactive T cells are important mechanisms in the development of autoimmunity. To date, the majority of functional studies have been performed on candidate genes but extension of this approach to the large number of loci identified by GWAS will likely yield further useful information on the molecular pathways involved in disease development and provide valuable insight into the mechanisms underlying T-cell tolerance. Such information may identify novel therapeutic targets for the prevention of T1DM. As shown by PPARγ in type 2 diabetes, a gene does not have to have a large effect on disease risk to be a good target for drug treatment. In this vein, there is currently considerable interest in developing inhibitors of LYP, to treat a range of autoimmune diseases [62], and compounds able to manipulate thymic insulin expression, which would have therapeutic potential in the treatment of T1DM [63].

Conclusion

Although considerable progress has been made in recent years to further our understanding of the genetic basis of type 1 diabetes, there is still a substantial proportion of inherited susceptibility that is, as yet, unexplained. Furthermore the causal variants at most of the validated risk loci remain to be identified, as do the mechanisms by which they influence disease risk. Future research aiming to address these gaps in our knowledge should integrate multiple approaches, including sequence-based fine mapping, whole-exome/whole-genome sequencing to identify rare variants, transcriptomics and mechanistic studies, gene network and pathway analysis, epigenetic regulation of gene function and the analysis of gene–gene and gene–environment interactions. Such studies may identify new therapeutic targets for T1DM and/or markers of extreme genetic risk that can be utilized in targeted primary prevention.

Obesity

The relationship between obesity and type 2 diabetes—the role of gut factors

Daniel S. Hsia and William T. Cefalu

Pennington Biomedical Research Center, Louisiana State University, Baton Rouge, LA, USA

Key points

- There are two key pathophysiologic defects underlying the progression from normal glycemic states to pre-diabetes and to type 2 diabetes: impaired insulin action due to insulin resistance and impaired β-cell function/insulin secretion.

- Gut hormones have important roles in the regulation of appetite, food intake, and insulin secretion.

- Glucagon-like peptide-1 (GLP-1) is released into the circulation after a meal and has various physiologic effects, including increasing insulin secretion, suppressing glucagon secretion, delaying gastric emptying, and suppressing appetite.

- Ghrelin is a 28-amino acid peptide hormone produced predominantly in the stomach and is the only known orexigenic gut hormone identified to date.

- The human gut microbiota contributes to multiple host processes including the defense against pathogens at the gut level, immunity (mediated through a number of signal molecules and metabolites), energy harvest, the development of the intestinal microvilli, maintenance of the intestinal barrier, and the synthesis of several vitamins.

- The gut microbiota's role in obesity and diabetes is still evolving, but likely involves differences in the diversity and composition of the gut microbiota among individuals leading to pathophysiologic changes such as varied energy harvest from the diet and low-grade chronic inflammation (due to intestinal permeability) which may contribute to insulin resistance.

- Unlike the human genome, the composition of the intestinal microbiota can be modified and may depend on specific dietary habits.

Introduction

The rise in obesity has been mirrored by the increase in the incidence of type 2 diabetes (T2DM). It is estimated that 60–90% of all people with T2DM are obese [1]. However, the majority of obese people do not develop diabetes, and thus obesity is only one factor that leads to the development of T2DM. There are several factors that have been recognized as major components of the obesity–diabetes relationship including insulin resistance, pancreatic dysfunction, and increased hepatic glucose production. Insulin resistance and relative insulin deficiency have been the factors most studied. In the early stages of insulin resistance, insulin secretion increases to compensate for defects in insulin action. Diabetes occurs when the insulin secretory capacity can no longer compensate for decreased glucose uptake due to insulin resistance [1]. There are both genetic and environmental contributions to the development of obesity and diabetes, and their rising prevalence necessitates further studies on modifiable factors and novel treatment options. A family history of diabetes puts an individual at higher risk for developing diabetes. However, studies such as the Diabetes Prevention Program demonstrated that lifestyle interventions including weight loss and exercise could reduce the incidence of diabetes in people at high risk [2]. In addition, with the introduction of incretin-based therapy for T2DM, it is clear that modulation of gut hormones can also affect glycemia. Gut hormones have important roles in the regulation of appetite, food intake, and insulin secretion. There is also an emerging role of gut microbiota on human health. The gut microbiota's role likely involves differences in the diversity and composition of the gut microbiota among individuals leading to pathophysiologic changes such as varied energy harvest from the diet and low-grade chronic inflammation (due to intestinal permeability) which may contribute to insulin resistance.

In this chapter, the focus will be on the role of gut factors, specifically gut hormones and the gut microbiota, which contribute to the pathophysiology of obesity and T2DM.

The relationship of obesity to insulin resistance and diabetes

The World Health Organization has deemed the increased prevalence of obesity and diabetes as a "twenty-first century epidemic" [3]. More than half of the world's population is considered overweight and being overweight is associated with several comorbidities such as T2DM, cardiovascular diseases, hypertension, dyslipidemia, respiratory diseases, osteoarthritis, and depression [3]. According to Ford et al., for every kilogram of weight gain, the risk of diabetes increases between 4.5 and 9% [4]. The relative risk for an obese individual to develop T2DM is 10-fold for women and 11.2-fold for men [5]. The most critical factor in the emergence of metabolic diseases is obesity.

One of the causal links between obesity and T2DM is the development of insulin resistance. Adipose tissue modulates metabolism by releasing free fatty acids (FFAs) and glycerol, hormones (including leptin and adiponectin), and pro-inflammatory cytokines [6]. It is well known that insulin sensitivity decreases with advancing age and is correlated with increasing body fat content. FFAs are an important link between obesity and insulin resistance. Acute elevations of plasma FFAs have been shown to increase insulin resistance in a dose-dependent manner in both diabetic and nondiabetic individuals [3]. Conversely, insulin-mediated glucose uptake and glucose tolerance improve with an acute decrease in FFAs after treatment with the antilipolytic agent acipimox [7]. Moreover, visceral and abdominal fat have been shown to have a negative correlation with insulin sensitivity [8] and thus have a prominent role in the pathogenesis of insulin resistance. Visceral fat cells are less sensitive to suppression of lipolysis by insulin [9]. FFAs produced by visceral adipocytes and entering via the portal circulation in the liver can induce hepatic insulin resistance, particularly by enhancing gluconeogenesis [3]. Gastaldelli et al. demonstrated that in patients with T2DM, visceral fat accumulation (independent of BMI) has a negative impact on glycemia through a decrease in peripheral insulin sensitivity and an enhancement of gluconeogenesis [10]. In muscles, the chronic decrease in glucose utilization due to the preferential use of lipids as an energy source limits the use of glucose from glycogen stores and inhibits glycogen synthase activity.

Ultimately, factors associated with obesity may lead to development of T2DM. There are two defects underlying this progression: impaired insulin action due to insulin resistance and impaired β-cell function/insulin secretion. In the early stages of insulin resistance, β cells in the pancreas secrete increased amounts of insulin to maintain euglycemia, thereby compensating for attenuated insulin action. However, after years of obesity and due to functional defects in insulin secretion, the β cells cannot maintain such high rates of insulin secretion, and the "relative" insulin deficiency given the degree of insulin resistance leads to impaired glucose tolerance and eventually T2DM [3,9]. This progression is illustrated in Figure 31.1 with obese diabetic individuals having the highest glucose and the lowest insulin levels.

Gut hormone regulation of appetite, food intake, and insulin secretion

Before we can understand the role of gut hormones in the pathophysiology and treatment of diabetes, we need to understand their major role in appetite, food intake, and insulin secretion. The gastrointestinal (GI) tract is the largest endocrine organ in the body and is believed to have an important role as a source of various appetite-regulating peptide hormones [11]. These hormones are thought to have a critical role in initiating and terminating eating behaviors. Postprandial satiety is believed to be regulated by communication between the gut and appetite-regulating centers in the brain, with the hypothalamus responsible for nutrient and energy sensing and corresponding adjustments in food intake [12]. This section will focus on the broad categories of pancreatic polypeptide-fold peptides and incretins.

Pancreatic polypeptide (PP)-fold peptides

The pancreatic polypeptide (PP)-fold family consists of neuropeptide Y (NPY), and the two gut hormones peptide tyrosine-tyrosine (PYY) and pancreatic polypeptide (PP); each shares a hair-pinfold motif necessary for receptor binding and has a distinct role in appetite regulation [13].

Peptide YY (PYY)

PYY is a full-length 36-amino acid peptide that is made and released from the L cells of the GI tract. PYY is processed in the circulation by dipeptidyl peptidase 4 (DPP-4), releasing the first two amino-acid residues and creating the active and dominant peptide PYY_{3-36}[14]. PYY_{3-36} appears to act in the hypothalamus as a satiety signal and has been shown to have anorexigenic effects in both normal weight and obese individuals. Circulating levels of PYY_{3-36} are influenced by meal composition and calorie content, and become elevated within 1 hour after feeding [12]. PYY_{3-36} infusion was found to reduce calorie intake similarly in obese subjects and in lean controls (30% vs. 31%) [15]. Since the anorexigenic effect of exogenous PYY_{3-36} is fully intact in obese individuals, PYY resistance is not thought to exist. This has encouraged longer-term weight loss studies involving chronic administration of PYY_{3-36} [12]. Significant increases in circulating PYY_{3-36} levels have also been reported post-GI surgery, possibly contributing to the initial and long-term maintenance of weight loss attributed to the procedure [14].

Pancreatic polypeptide (PP)

PP is a 36-amino acid anorexigenic peptide primarily made and released from the endocrine pancreas, and to a lesser extent, from the colon and rectum. PP is regarded as part of the "ileal brake," which slows the transit of food through the gut. PP slows gastric emptying, inhibits pancreatic exocrine secretion and reduces gallbladder contraction [16]. The main stimulus of PP release is the ingestion of food. In humans, postprandial levels of PP are proportional to calorie intake and levels remain elevated for approximately 6 h after eating [13]. PP release is inversely correlated to body weight, with obese subjects displaying reduced postprandial PP secretion, and anorexic individuals displaying elevated postprandial levels [13]. Peripheral PP administration leads to an increase in energy expenditure and a reduction in body weight in rodents in addition to a reduction in appetite and food intake in both lean and obese humans [12]. Although the exact mechanism of PP's effect is still unknown, these data support its potential as an anti-obesity therapy.

Incretins

Incretins are gut-derived factors that stimulate insulin release and are produced by selective posttranslational cleavage of proglucagon, a 160-residue peptide, expressed in the α-cells of the pancreas and L cells of the intestine and the CNS [13].

Glucagon-like peptide (GLP-1)

GLP-1 is a 29-amino acid polypeptide secreted from the L cells of the distal gut and is a cleavage product of proglucagon. The two synthesized forms of GLP-1 are $GLP-1_{1-37}$ and $GLP_{1-36\ amide}$, with further cleavage required to produce the two bioactive fragments, $GLP-1_{7-26\ amide}$ and $GLP-1_{7-37}$ [17]. GLP-1 is released into the circulation after a meal and has various physiologic effects, including increasing insulin secretion, suppressing glucagon secretion, delaying gastric emptying, and suppressing appetite [14]. In addition, in preclinical studies, GLP-1 has been found to stimulate β-cell proliferation, to enhance the differentiation of new β cells in the pancreatic duct epithelium, and to inhibit apoptosis of β cells.

GLP-1 and GIP are responsible for what is known as "the incretin effect," which is the enhanced secretion of insulin in response to oral administration of glucose compared with intravenous administration of glucose [18]. GLP-1 is released in the gut in proportion to ingested calories. In both lean and obese humans, peripherally administered GLP-1 has been shown to exert anorexigenic effects, with other possible influences on food intake being linked to a reduction in gastric emptying and a suppression of gastric acid secretion. Obese individuals have been reported to elicit delays in the postprandial release of GLP-1, and thus present with reduced circulating levels of the peptide. Because of inactivation and clearance by the enzyme DPP-4, the half-life of GLP-1 is an estimated 5 min, thus presenting a major hurdle to its possible therapeutic utility. Currently, approaches seek to take advantage of GLP-1 effects by either extending the half-life of GLP-1 with endogenous inhibition of the responsible enzyme or providing a molecule that resists the degradation. Such pharmacologic approaches are realized with the development of GLP-1 analogues and DPP-4 inhibitors. Inhibition of DPP-4 has had useful applications in the treatment of T2DM, but less promising results have been demonstrated in terms of its anti-obesity utility.

Oxyntomodulin (OXM)

OXM shares the same precursor molecule as GLP-1, is co-secreted with GLP-1 from the L cells of the distal small bowel following feeding, and its release is proportional to the meal calorie content [14]. OXM inhibits gastric acid secretion and gastric emptying. OXM acts as a dual agonist at the GLP-1 and glucagon receptors [14]. GLP-1 and glucagon are known to suppress food intake and glucagon can increase energy expenditure. This combination of decreased food intake and increased energy expenditure would be expected to enhance weight loss but no OXM analogues have yet to be approved for human use. Similar to GLP-1, the potential therapeutic utility of OXM may, in part, be hindered due to its inactivation by DPP-4. Although OXM has a less potent incretin effect compared to GLP-1, the effects of OXM on food intake in humans are more potent with reportedly less nausea than GLP-1 [12].

Glucose-dependent insulinotropic polypeptide (GIP)

Initially called gastric inhibitory polypeptide due to its inhibitory effects on gastric acid secretion in dogs, this 42-amino acid polypeptide was renamed glucose-dependent insulinotropic polypeptide to reflect its role in glucose metabolism [19]. GIP is secreted from K cells after eating a meal and is inactivated rapidly by DPP-4. Along with GLP-1, GIP acts as an incretin to potentiate glucose-stimulated insulin release. GIP has direct anabolic effects on adipose tissue, including stimulation of glucose import, fatty acid synthesis, lipogenesis, and inhibition of lipolysis [14]. GIP indirectly influences energy balance and body weight due to its effects on lipid metabolism; however, direct infusion of GIP into healthy male subjects does not affect appetite, energy intake, or energy expenditure [20].

Cholecystokinin (CCK)

CCK was the first gut hormone shown to affect appetite. Levels of CCK in the plasma rise within 15 min of meal initiation, and CCK reduces food intake in a dose-dependent manner [12,21]. CCK is predominantly produced and released by the L cells of the duodenum and jejunum. It exists in several bioactive forms including CCK-8, CCK-22, CCK-33, and CCK-58; the numerical suffix denotes the number of amino acids [21]. CCK has several roles including: stimulation of gallbladder contraction, pancreatic enzyme secretion, and inhibition of gastric emptying. CCK is also present in the hypothalamus, predominantly in the median eminence and ventromedial nucleus, and is the most abundant neuropeptide in the CNS [12]. Administration of CCK has been shown to reduce food intake in both rodents and humans, which has led to its investigation as a therapeutic target for obesity. However, compensatory increases in meal frequency, tolerance after infusion, and its short half-life have limited CCK's therapeutic utility [12].

Ghrelin

Ghrelin is a 28-amino acid peptide hormone produced predominantly in the stomach and is the only known orexigenic gut hormone identified to date. Ghrelin binds to the growth hormone secretagogue receptor and is also expressed in the NPY neurons of the hypothalamus. Circulating ghrelin levels increase with fasting, encouraging food intake, and then decrease after a meal [14]. Administration of ghrelin has been shown to induce appetite and food intake, suggesting it may be useful therapeutically to reverse pathologic states of cachexia [13]. Plasma ghrelin levels correlate inversely with body weight, and diet-induced weight loss increases circulating levels of ghrelin in obese individuals [22]. Also, the expected postprandial fall in circulating ghrelin levels is attenuated, or even absent in obese people, suggesting that ghrelin has a role in the pathophysiology of obesity [12]. Pharmacologic blockage of ghrelin results in decreased food intake and body weight in rodents, and ghrelin- or ghrelin receptor-deficient rodents are resistant to diet-induced obesity [12]. Thus, ghrelin antagonism may be a promising strategy to treat obesity.

Other related hormones
Amylin

Islet amyloid polypeptide (IAPP), also known as amylin, is a 37-amino acid peptide synthesized in pancreatic β cells that is co-secreted with insulin in response to nutrient intake. It is also produced in smaller amounts by enteroendocrine cells and enteric neurons within the gastrointestinal tract [23]. Amylin is briefly mentioned here because of its role in glucose regulation and food intake. Amylin decreases postprandial blood glucose levels through inhibition of gastric emptying and suppression of glucagon secretion. Activation of amylin receptors in the area postrema in the brain induces satiety and leads to decreased food intake [23].

Role of gut hormones in obesity and type 2 diabetes

There is increasing evidence that the function and efficacy of gut hormones change in the obese individual [19]. Fasting CCK levels as well as the normal postprandial rise in CCK are lower in morbidly obese subjects compared with either obese or lean controls [24]. As for PYY_{3-36}, fasting levels are inversely proportional to body mass and the postprandial rise in PYY_{3-36} is blunted in obesity. Obese humans have been reported as needing to consume twice as many calories to achieve the same plasma PYY_{3-36} levels as lean controls [25]. Therefore, PYY_{3-36} deficiency has been proposed to be involved in the maintenance of obesity by reducing satiety. While basal ghrelin levels are lower in obese compared to lean individuals [26], food intake is higher in obese compared to normal weight individuals when low doses of ghrelin are given, indicating that obesity increases ghrelin sensitivity [27]. Incretin levels also change in obesity. Fasting GLP-1 is reduced, and its response to an oral glucose load is blunted [19]. The reduction in GLP-1 may contribute to the impaired glucose tolerance that occurs in obesity. Changes in GIP levels have not been consistently observed in obese individuals; however, in theory increased

GIP levels may propagate obesity by increasing fatty acid uptake into adipose tissue [19].

Studies by Nauck et al. have shown that the incretin effect is severely reduced or lost even in relatively lean type 2 diabetes patients (BMI ~25 kg m^{-2}) [28]. Knop et al. demonstrated a similar impairment in the incretin effect in individuals with T2DM as well as those with diabetes secondary to chronic pancreatitis, indicating that an impaired incretin effect is likely a consequence of developing diabetes rather than a cause of T2DM [29]. Interestingly, infusion of large amounts of GLP-1 resulted in near normal insulin responses in individuals with T2DM whereas infusion of GIP has no significant effect [30]. This has led to the development of DPP-4-resistant analogues (such as exenatide and liraglutide) as well as inhibitors of DPP-4 (such as saxagliptin, sitagliptin, and vildagliptin) to protect GLP-1 from degradation and to augment its insulinotropic activity [31–33]. New approaches are seeking to extend the half-life of GLP-1 with the development of more stable GLP-1 analogues such as extended release exenatide and albiglutide.

The role of microbiota in obesity and diabetes

Since the announcement of the Human Microbiome Project [34] in 2007, relationships between gut bacteria and a variety of health conditions have been reported. Staying with the gut theme for this chapter, we switch our focus to another emerging contributor to the pathophysiology of obesity and diabetes: gut microbiota.

Gut microbiota in health and disease
The human fetus is microbiologically sterile and is colonized by bacteria from the mother and the surrounding environment at birth. The initial microbiota is relatively unstable and undergoes dramatic changes before stabilizing around weaning [35]. The human gastrointestinal (GI) tract contains a complex consortia of trillions of microorganisms (approximately 1×10^{13} to 1×10^{14}, biomass > 1 kg), thousands of bacterial phylotypes, as well as hydrogen-consuming methane-producing microorganisms with a collective genome (termed the microbiome), the majority of which resides in the colon [36]. As a whole, the microbiome represents more than 100 times the nucleotide content of the human genome. Thus, the human "metagenome" consists of a mixture of genes embedded in the human genome and in the genomes of our microbial partners. The microbiota and its microbiome provide humans with additional gene products that we lack, and these serve many functions in maintaining our bodies' homeostasis. The human gut microbiota may be regarded as a "microbial organ" within the gut, which contributes to multiple host processes including the defense against pathogens at the gut level, immunity (mediated through a number of signal molecules and metabolites), energy harvest, the development of the intestinal microvilli, maintenance of the intestinal barrier, and the synthesis of several vitamins.

Moreover, accumulating evidence indicates that the gut microbiota plays a crucial role in conditions such as obesity, diabetes, nonalcoholic fatty liver disease, inflammatory bowel disease (IBD), and even cancer [36].

Gut microbial composition among healthy humans is influenced by host genotype, diet, age, and gender; and it appears that a variety of diseases and drugs can modulate microbiome composition and activities.

In spite of the large microbial diversity in humans, there are only a small number of microbial phyla that are numerically dominant: Firmicutes (~60%), Bacteroidetes (~15%), Actinobacteria (~15%), Verrucomicrobia (~2%), Proteobacteria (~1%), and Methanobacteriales (~1%) [36]. Interestingly, adult monozygotic and dizygotic twins may have a similar microbiota even if they live in different locations [37]. These findings suggest that a shared environment early in life and the maternal inoculum have a large impact upon the gut microbiota in adulthood.

The relationship of gut microbiota to energy balance, obesity, and obesity-related disorders
Gut microbiota exert a crucial role in the development of fat mass and altered energy homeostasis. The earliest evidence supporting this hypothesis came from a study showing that germ-free mice (mice raised in the absence of any microorganisms) are leaner compared to mice with microbiota since birth. Importantly, the colonization of germ-free mice with a gut microbiota caused an increase in fat mass and insulin resistance. This study showed that the gut microbiota constitute a novel environmental factor that regulates fat storage [38]. Moreover, Ridaura et al. demonstrated that an increased adiposity phenotype was transmissible in mice via an ingested fecal sample from an obese human. Co-housing these obese mice with lean mice prevented the increased adiposity phenotype when the mice were fed a low saturated fat, high fruits and vegetables diet. Rescue correlated with invasion of members of the Bacteroidetes species from the microbiota of the lean mice into the microbiota of the obese mice. These findings reveal transmissible, rapid, and modifiable effects of diet-by-microbiota interactions [39].

Obesity is recognized to be associated with changes in the gut microbiota diversity and composition. In addition, individuals with a low bacterial richness/low gene count (<480,000 genes) in their microbiota have more overall adiposity, insulin resistance, dyslipidemia, and a more pronounced inflammatory phenotype when compared with individuals with high bacterial richness [40]. Various studies have characterized the gut microbiota in mouse models of obesity, with many of the results highlighting an increase in Firmicutes and a decrease in Bacteroidetes associated with obesity [41,42]. Early gut microbial composition has been shown to be predictive of the development of obesity in a variety of populations: small children [43], obese adolescents [44], and pregnant women [45]. However, most of these studies have been performed in a limited number of subjects, using microbial methods that were not state-of-the-art according to current standards, and were mostly retrospective in design. In addition, a study by Duncan et al.

found no relationship between obesity and the proportions of Bacteroides and Firmicutes in obese men [46]. Schwiertz et al. determined lower ratios of Firmicutes to Bacterodetes in overweight human adults compared to lean controls [47]. Thus in humans, the increase in the Firmicutes/Bacteroidetes ratio as it relates to obesity continues to be one of active study and it is likely that our understanding of what specific microbial groups contribute to obesity risk will continue to evolve.

In terms of T2DM, Larsen et al. demonstrated a significantly reduced amount of Firmicutes in people with type 2 diabetes compared with a control group. Moreover, the ratio of Bacteroidetes to Firmicutes positively correlated with plasma glucose concentration but not with body mass index [48]. Comparisons of gut microbiota between obese and lean individuals with or without T2DM revealed that people with type 2 diabetes had reduced levels of *Faecalibacterium prausnitzii*, a member of the phylum Firmicutes. This reduction correlated with increased levels of inflammatory markers and suggests that *F. prausnitzii* potentially functions as a probiotic to alleviate insulin resistance [49].

Potential mechanisms of disease related to gut microbiota

There are multiple features of the gut microbiota that can promote obesity and insulin resistance (Figure 31.2). One of the proposed mechanisms of how the gut microbiota influences obesity is that the gut microbiota have the capacity to increase the energy harvested from the diet. Increased energy harvest correlates with increased fermentation capacity of the microbiota and increased levels of short chain fatty acids (SCFAs) [35]. SCFAs are produced by the colonic microbiota through anaerobic fermentation. The chief substrates for colonic fermentation are undigested carbohydrates, namely dietary fiber and resistant starch [50]. Acetate, propionate, and butyrate are the main SCFAs produced by the microbiota in the colon [51]. Normal colonic epithelia derive 60–70% of their energy from SCFAs, particularly butyrate. Propionate is largely taken up by the liver and is a precursor for gluconeogenesis, liponeogenesis and protein synthesis. Acetate enters the peripheral circulation and is a substrate for cholesterol synthesis. Analysis of fecal SCFA concentration in a group of lean and obese subjects showed significantly higher total SCFA content in obese subjects [47]. Another smaller study of 11 lean and 11 overweight or obese individuals showed a positive correlation between fecal SCFAs and Firmicutes abundance. Fecal SCFAs were higher in the overweight/obese group despite similar dietary intakes [50]. Studies have shown that mice deficient in either of the SCFA receptors, Gpr41 and Gpr43, are leaner than their wild-type counterparts, further implicating SCFAs in the development of obesity [35].

Studies have demonstrated that the gut microbiota can also trigger inflammation, thereby possibly playing a major role in the onset of insulin resistance and T2DM [41]. Gut microbiota-derived lipopolysaccharide (LPS) is a key molecule involved in the early development of inflammation and metabolic diseases. LPS is a powerful pro-inflammatory molecule from the cell wall of Gram-negative bacteria and is continuously produced in the host gut with the death of Gram-negative bacteria [41]. High-fat feeding has been shown to not only increase fatty acid levels but to also increase circulating LPS levels [35]. Direct evidence for the role of LPS was demonstrated by chronic infusion of LPS over a 4-week period in chow-fed mice, which led to increased adiposity, increased macrophage infiltration in adipose tissue, hepatic inflammation, and hepatic insulin resistance [52].

Emerging evidence suggests that gut barrier disruption could be responsible for the metabolic endotoxemia present in obesity and T2DM, as has been shown particularly in models of Crohn's disease [41]. Conversely, modulating gut microbiota to reduce endotoxemia may improve diabetes risk factors. For instance, an increase in the gut barrier-protective Bifidobacteria improves high-fat-diet-induced diabetes in mice through a mechanism associated with decreased endotoxemia [53]. Studies have demonstrated that the increase in gut permeability observed in obese mice may be associated with an alteration in the expression, localization, and distribution of two tight-junction proteins (occludin and zonula occludens-1) in the small intestine [41]. Moreover, LPS is taken up from the gut lumen either via a chylomicron-dependent mechanism and/or through tight junctions. The gut microbiota regulates gut permeability by at least two mechanisms—via either GLP-2 or the endocannabinoid system [35]. Treatment of obese *ob/ob* mice with prebiotics induces endogenous GLP-2 levels that are associated with improved gut permeability and reduced plasma LPS levels. Pharmacologic inhibition of GLP-2 signaling negated the effects of prebiotics, establishing a direct link between GLP-2 and gut permeability [54]. Prebiotics can reduce colonic expression of the endocannabinoid receptor CB1 in obese mice, and treatment with a CB1 receptor antagonist prevented degradation of tight-junction proteins and reduced plasma LPS levels [55].

Intestinal alkaline phosphatase (IAP) is known to be involved in the breakdown of dietary lipids and also plays an important role in LPS detoxification by dephosphorylating the lipid portion of LPS. Obesity appears to be associated with a decrease in IAP activity. Thus, modifications of the IAP activity by a high-fat diet, gut microbiota, or other compounds may contribute to the alterations in the gut barrier functions in obesity and T2DM. Moreover, an increase in IAP activity is associated with a reduction in metabolic endotoxemia [41].

In a recent study, Vrieze et al. demonstrated that infusion of intestinal microbiota from lean healthy donors temporarily improves insulin sensitivity in individuals with metabolic syndrome [56]. Although this link is well established in a mouse model of obesity, more studies are needed to confirm the involvement of gut microbiota alterations and gut barrier functions in the metabolic endotoxemia associated with obesity and T2DM in humans.

Dietary interventions that alter the gut microbiota and host metabolism

Unlike the human genome, the composition of the intestinal microbiota can be modified and may depend on specific dietary habits. De Filippo et al. compared the gut microbiota in a group of children living in Burkina Faso, a country in West Africa (diet low in fat and animal protein; rich in starch, fiber, and plant polysaccharides; and predominantly vegetarian) and in a group living in Italy (diet high in animal protein, sugar, starch and fat, and low in fiber). Actinobacteria and Bacteroidetes were more represented in the microbiota of children from Burkina Faso than from Italy (10.1% vs. 6.7% and 57.7% vs. 22.4%, respectively), whereas Firmicutes and Proteobacteria were more abundant in the children from Italy than in children from

Burkina Faso (63.7% vs. 27.3% and 6.7% vs. 0.8%, respectively) [57]. In a representative animal model created by transplanting fresh or frozen adult human fecal microbial communities into germ-free mice, the structure of the microbiota was shifted within a single day when these mice were switched from a low-fat, plant polysaccharide-rich diet to a high-fat, high-sugar "Western" diet [58]. Moreover, individuals with a low bacterial gene count in the gut subjected to a 6-week energy restricted high-protein diet developed an increase in gene richness in the gut and subsequently led to a significant decrease in adiposity measures (hip circumference and total fat mass) and circulating cholesterol [59]. This plasticity of the gut microbiome may allow manipulation of certain gut microbiota associated with host disease, or conversely, enable enhancement of gut microbiota promoting health [36]. Figure 31.3 illustrates some of the potential beneficial effects of antibiotics, prebiotics, and probiotics on some metabolic disturbances related to obesity and T2DM.

Among the tools to modulate the gut microbiota, prebiotics (i.e., nondigestible food ingredients that benefit the host by selectively stimulating the growth and/or activity of one or a limited number of the bacteria in the gut) [60], and probiotics (i.e., live microorganisms which, when given orally in quantities adequate to allow colonization of the colon, confer a health benefit to the host) [61], are the most important. Gut microbiota modulations using prebiotics (i.e., short-chain inulin-type fructans, oligofructose, or wheat-derived arabinoxylan oligosaccharides) improve gut barrier functions, metabolic endotoxemia, and inflammation in obesity and T2DM [41].

Incretin hormones potentiate glucose-induced insulin secretion in response to a meal and are responsible for approximately half of the insulin response after food ingestion [35]. The gut microbiota can affect incretin function as demonstrated by an increased number of L cells in rats fed oligofructose (OFS)

prebiotics, which promote increased levels of Bifidobacterium [62]. However, this relationship has not been established in humans and the role of the prebiotic on GLP-1 production independent of Bifidobacterium is unclear.

In mice, glucagon-like peptide-2 (GLP-2) antagonist treatment completely blocked the improvements in gut barrier function and the reductions in metabolic endotoxemia and inflammation induced by prebiotics, suggesting that the beneficial gut microbiota changes work through a mechanism involving GLP-2-driven improvement of gut barrier functions in obesity and T2DM [54]. Other preclinical studies have demonstrated that prebiotic-induced changes in the gut microbiota also modulate GLP-1, PYY, GIP, and ghrelin [41]. In human studies, the gut fermentation of nondigestible carbohydrates increases satiety after a meal and decreases food intake [63]. Parnell and Reimer demonstrated that gut microbiota modulations (after 12 weeks of prebiotic treatment) modulated ghrelin and PYY in overweight and obese patients and could thereby promote weight loss and improve glucose regulation [64].

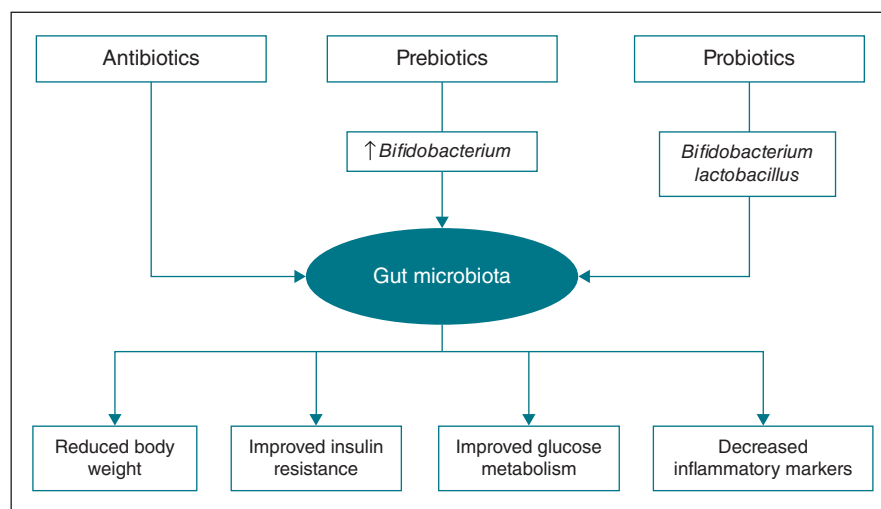
Among the metabolites produced by the gut microbiota, the SCFAs could be a link between the gut microbiota and changes in gut peptides levels. Modifications in acetate, butyrate, propionate, and total SCFA levels occurred in the fecal samples of healthy humans treated with xylo-oligosaccharides alone or with an inulin/xylo-oligosaccharide mixture. Furthermore, an inulin/xylo-oligosaccharide mixture decreased plasma LPS levels and reduced the pro-inflammatory effects of LPS on cytokine gene expression in the blood of healthy humans [65]. Studies in mice demonstrated that administration of a probiotic promoted the release of the hormone GLP-1, resulting in reduced food intake and improved glucose tolerance [66]. More studies are needed to unravel the beneficial effects of prebiotics and probiotics in obese and type 2 diabetic patients.


Figure 31.3 The modification of gut microbiota with antibiotics, the relative increase in Bifidobacterium by the use of prebiotics, and the use of probiotics such as Bifidobacterium and Lactobacillus shows beneficial effects on metabolic disturbances. Summary

More and more evidence is emerging as to the importance of gut factors in the development of obesity and diabetes. Gut hormones have important roles in the regulation of appetite, food intake, and insulin secretion. Thus many of these hormones have been targets of pharmacotherapy for the treatment of obesity and diabetes. In particular, GLP-1 agonists have been an important addition to the armamentarium used to treat diabetes. Gut hormones are also becoming increasingly important as we begin to better understand the metabolic changes that occur after bariatric surgery. Moreover, gut microbiota have been implicated in a variety of human diseases including obesity and diabetes. They have a role in the defense against pathogens at the gut level, energy harvest, the development of the intestinal microvilli, maintenance of the intestinal barrier, and the synthesis of several vitamins. Currently, much of the data in humans remains controversial as to the cause and effect of the intestinal microbiota. However, the potential to alter microbiota as a means to improve health remains an important field of research.

Key points

- Total daily energy expenditure is comprised of resting metabolic rate (60–70%), diet-induced thermogenesis (10%) and structured and spontaneous activity thermogenesis (20–30%).

- Up to 85% of resting metabolic rate can be explained by fat-free mass, fat mass, age, and sex. Most of the remaining RMR variance is biologically (genetically) determined.

- Potential physiologic mechanisms leading to weight gain include low metabolic rate, low levels of physical activity, low sympathetic nervous system activity, and low fat oxidation, although more longitudinal data is still required.

- However, the major trigger of weight gain is excess food intake driven by the ubiquitous presence of cheap and palatable food.

- Given solid advances in gene targeting and related technologies, knockout and transgenic mouse models have identified molecular pathways that stimulate thermogenic programs. Further examination of these pathways including "browning" of white adipose tissue may prove useful for identifying new therapies for treating human obesity.

- Using analysis of covariance is the best way to normalize energy expenditure data for metabolic size and to compare differences between groups before and after an intervention.

Introduction

Body weight is an intricate balance between energy intake (calories consumed) and energy expenditure (calories burned). When energy intake exceeds energy expenditure over an extended period of time, body weight is gained and may lead to overweight and obesity. Whether the culprit of this weight gain is increased energy intake or reduced energy expenditure (EE) is unknown, but it is likely to be a combination of both with proportions of each varying from case to case. Since Lavoisier's famous statement "*la réspiration est donc une combustion*" in 1790, generations of scientists have studied how the human body metabolizes energy and the most precise method to measure this metabolism. Progressing towards the development of the metabolic chamber in the 1970s and doubly labeled water in the 1980s, many research laboratories in the world can now precisely and accurately assess EE in laboratory and free-living conditions. This chapter will review the methods by which EE can be measured in humans and the physiologic and molecular mechanisms linking EE with excess weight gain. Lastly, given that metabolic carts are now widely available in research and clinical settings, an updated summary of the best way to analyze EE data in humans is provided.

Methods of measuring energy expenditure

Several methods have been developed to measure daily EE in humans. The most accurate methods involve continuous measurement of heat output (direct calorimetry) or gas exchange (indirect calorimetry) in individuals confined to small metabolic chambers. Confined individuals, however, are unable to continue activities related to daily living. As such, a number of field methods have been developed for this purpose ranging from the most accurate, doubly labeled water, to the less accurate, portable devices and self-reported questionnaires.

Direct calorimetry

Heat is the ultimate fate of all the body's metabolic processes; EE can therefore be measured directly as heat loss using direct calorimetry [1]. Direct calorimetry involves putting individuals in a small insulated chamber where heat released in the form of dry heat (radiative and convective heat losses ∼80%) or evaporative heat (heat loss from the evaporation of water from the skin

and lungs ~20%) is measured. Direct calorimetric methods have largely become obsolete as they are expensive to build, run and maintain. Thus only specialized laboratories where direct heat loss values are required still have such capacity.

Indirect calorimetry

Under normal physiologic conditions, neither oxygen nor carbon dioxide are stored in the body. Therefore an indirect way of measuring EE is to measure oxygen consumption, carbon dioxide production, and nitrogen excretion. Presently, indirect calorimetry is widely used in normal and diseased conditions and is mainly performed using the open-circuit system which can measure EE over several hours or days in a respiratory chamber [1,2]. The open-circuit system can be performed using a mouthpiece, mask, transparent hood, or canopy. The individual inhales ambient air with a known composition. Changes in oxygen and carbon dioxide percentages in the expired air compared with the percentages in inspired ambient air reflect ongoing energy metabolism. During the last three decades, the indirect calorimetry method has been applied to confined rooms called respiratory or metabolic chambers [3]. These calorimeters are large enough (12,000–30,000 L) for an individual to live comfortably in for a few days, although typically most laboratories perform the measurement for 24 hours. Respiratory chambers can measure various components of daily EE including sleeping metabolic rate, the energy cost of arousal, the thermic effect of food, and the energy cost of spontaneous physical activity. With an average CV of 1–3% [4], respiratory chambers are used as the gold standard to validate newer methods of measuring EE such as doubly labeled water [5,6]. Metabolic chambers have become increasingly available in the past decade with more than 25 chambers worldwide in 2012 (there were only two worldwide in 1970).

Doubly labeled water

Developed by Lifson, the doubly labeled water (DLW) method is a form of "indirect" calorimetry and is based on the differential elimination of two nonradioactive isotopes, deuterium (^{2}H) and ^{18}oxygen (^{18}O) from body water following a single dose of these stable isotopes [7]. Oxygen tagged with the ^{18}O tracer will equilibrate not only in body water but also in circulating bicarbonate and expired CO_2. Over time, the ^{18}O tracer in body water will decrease as CO_2 is expired and water is lost in respiration, perspiration, and urine. The hydrogen molecule tagged with the ^{2}H tracer will distribute only in the circulating water and bicarbonate and over time will decrease as water is lost. The isotopes are eliminated at different rates from the body, and thus the difference between the two elimination rates is a measure of CO_2 production, from which total daily EE can be calculated using classical indirect calorimetry equations [6].

The major advantage of the DLW method is that it provides an integrated measure of total CO_2 production over 4 to 21 days, yet requires only periodic sampling of blood, saliva, or most commonly, urine. Importantly, the DLW method

allows individuals to be studied in the free-living state and has been validated repeatedly with excellent accuracy (1–3%) and precision (2–8%) against the gold standard indirect calorimetry [5,6]. The method is noninvasive and can be used in pregnant women [8], infants [9] and children, subjects with gastrointestinal disorders and the elderly. Limitations of DLW are the purchasing of expensive isotopes (2H), the measurement of analytical isotopic enrichments are labor intensive, and the inability to quantify substrate oxidation.

Portable devices

Pedometers and accelerometers are devices worn by an individual to quantify movement under free-living conditions. Pedometers assess displacement of the body with a single stride, with the output presented as steps taken or steps per day. Pedometers are economically feasible and therefore are easily applied in large populations. However, pedometers cannot discriminate between different activities or the intensity of physical activity and do not provide any quantification of EE per se.

Accelerometers assess and quantify the motion and movement associated with physical activity. Acceleration is the change in velocity with respect to time (m s^{-2}), enabling accelerometers to quantify the intensity of movement. The majority of accelerometers are unilateral and sensitive to movement in the vertical plane (uniaxial accelerometer), but some are also sensitive to movements in the antero-posterior and/or lateral plane (triaxial accelerometer). Accelerometers provide a count value which describes the intensity, frequency, and duration of physical activity. However, the reliability of accelerometers to estimate daily EE varies from no correlation of activity counts to EE [10] to triaxial accelerometers explaining up to 90% of EE [11]. Such variability can be explained by several reasons including that validation experiments are usually performed in laboratory settings, with protocols consisting of treadmill-based locomotion whereas accelerometers are usually worn in free-living conditions. Also, it may be due to differences in monitors, duration (number of days), protocols (number and placement of monitors), methods of analysis and data interpretation [12]. It appears that pedometers and accelerometers provide useful indicators of physical activity levels but interpretation should be restricted to monitor-based output (e.g. steps taken, count value), as the validity of derived measures including total EE is often compromised [12].

Questionnaires and activity logs

Activity questionnaires, including interviews and diaries, are the most common tools for assessment of physical activity, with the energy cost of each activity estimated from energy expenditure tables. This method, called the factorial method, although cheap and easy to apply takes extended amounts of time for data analysis. Factorial assessments of a subject's EE require that the type and duration of physical activities be recorded over a specified time period (usually several days). The energy cost of

each activity is estimated using energy-equivalent tables and multiplied by the time spent doing each activity. These values are then summed to derive an estimate of the EE related to the activity. As expected, this method is time-consuming for both participants and investigators and substantial errors can be incurred due to both inaccurate recall by individuals and the availability of numerous energy coefficients that can be applied to determine the energy cost of the activities. Comparisons with the doubly labeled water method generally show low correlations with systematic underestimates, overestimates, or agreement at the group level but large error at the individual level [13].

Components of energy expenditure and their relevance for human obesity

Total daily energy expenditure varies (TDEE) substantially in humans such that two adults with the same body size and body composition can have an EE that varies by as much as 1500 kcal d^{-1}. The largest determinants of EE are weight, specifically fat-free mass, age, and sex [3]. Height and weight are all associated with higher TDEE, whereas TDEE declines with older age. Across all ages TDEE is approximately 11% higher in males, after adjusting for body size [14]. Understanding the inherent variability in EE will potentially assist in elucidating dynamics of excess weight gain and obesity. Such variability in daily energy requirements may be attributed to differences in the three components of EE: basal metabolic rate (BMR), the thermic effect of food and especially the energy cost of physical activity, consisting of both exercise and nonexercise activity thermogenesis (Figure 32.1).

Resting metabolic rate

Resting metabolic rate (RMR), accounting for 60–70% of TDEE, represents the energy required to maintain essential functions of the body's vital organs and varies among individuals of different body size and body composition [3]. Under standard conditions, RMR is measured using the ventilated hood technique while the participant is awake and resting in a thermoneutral environment following an 8–12-hour fast and at least 12-hour abstinence from exercise and smoking. It has long been recognized that there is a close relationship between RMR and body size; this association has led to the development of widely used equations to predict RMR using height and weight from the classical Harris and Benedict equation proposed in 1919 [15], the Schofield equation in 1985 [16], and many others [17–19]. Up to three quarters of the variance in RMR is determined by fat-free mass [20,21] and to a lesser extent, by fat mass, sex, and age. Together, these four components explain up to 85% of the interindividual variance in RMR [20,21]. Eleven percent of the remaining variance can be further explained by family membership, therefore genetic factors also influence the variability in RMR [20]. It is also important to mention that
Figure 32.1 The components of daily energy expenditure. Total daily energy expenditure is comprised of three major physiologic compartments: (1) *Resting (basal) metabolic rate* (60–70%) which includes the energy cost required to maintain the integrated systems of the body and homeostatic temperature at rest. BMR can be divided into sleeping metabolic rate and the energy cost of arousal; (2) *Diet-induced thermogenesis* (10%) is the increase in energy after a meal associated with the digestion, absorption, and storage of food; and (3) activity thermogenesis (30%), being the energy expended during volitional (structured exercise) and nonvolitional activities. The latter is termed spontaneous physical activity or nonexercise activity thermogenesis (NEAT) and includes the energy cost of sitting, maintaining posture, fidgeting, shopping, and so on. Total daily energy expenditure and its components can be measured in the laboratory in standard conditions and in free-living conditions. The left panel indicates the measurement of daily energy expenditure for 24 hours in a room calorimeter and the right depicts the total daily energy expenditure measured over 7–10 days using the doubly labeled water method. The doubly labeled water method has the advantage of measuring daily energy expenditure in free-living conditions and therefore the amount of NEAT can be accurately assessed.

fat-free mass is not metabolically uniform since it is composed of different tissue and organs, and thus tissue or organ-specific metabolic rates will contribute to further variability in measured RMR [22–24].

Diet-induced thermogenesis

Diet-induced thermogenesis, or the thermic effect of food (TEF) is the increase in EE associated with the digestion, absorption, and storage of food. It accounts for 5–15% of TDEE and is therefore the smallest component of daily EE. TEF is the most difficult and least reproducible component of EE to measure [4,25]. In contrast to RMR with a CV of 3–8% [26], the CV of TEF measured with indirect calorimetry is typically around 20% [25,27]. The measurement of TEF is performed in response to a test meal, either continuously or intermittently for 3–6 hours, under similar conditions to an RMR (fasting conditions at rest in a thermoneutral environment). Compared to a continuous measurement of TEF, intermittent measures of TEF have been shown to give a 50% lower response but a more replicable measure [27]. The duration of measurements

also contributes to variation in TEF, with shorter measurements (<5 h) yielding greater errors [28].

Given the variability in measuring TEF, its role in the etiology of obesity is still not clear. A review of 49 studies comparing TEF in lean vs. overweight/obese individuals reported that obesity was associated with an impaired TEF response, and was related to the degree of insulin resistance [29]. However, a subsequent review of 50 studies identified substantial shortcomings in the methods used to measure and calculate TEF, questioning the role of a low TEF in the development of obesity [30]. Indeed, the measurement of TEF is influenced by a myriad of factors including meal size and delivery (standard meal or glucose load), nutrient composition (protein exerts higher TEF), palatability of the meal, meal frequency as well as an individual's genetic background, age, physical activity, and sensitivity to insulin [29–32].

Importantly, prospective studies have not identified a relationship between TEF and weight change [25,33]. It is safe to say that a decrease in TEF equates to only a small amount of calories and therefore is very unlikely to explain significant degrees of obesity.

Activity thermogenesis

Activity thermogenesis, defined as body movement produced by skeletal muscle resulting in EE, comprises two distinct types of energy thermogenesis—the energy expended during exercise or structured physical activity (normally planned activities) and the energy expended in all other nonexercise activities (normally unplanned activities). The latter was described as spontaneous physical activity [34], and subsequently called Non Exercise Activity Thermogenesis (NEAT) by Levine and colleagues in 1999 [35]; it includes activities such as the energy cost of sitting, standing, walking, talking, fidgeting, and so on. Of course the hypothesis that reduced physical activity is the cause of the worldwide obesity epidemic is an attractive one. However, the amount of structured physical activity has remained relatively stable over the years and thus occupational physical activity has an even greater potential to impact energy balance [36]. Moreover, for the vast majority of people living in developed countries, exercise-related activity thermogenesis is negligible. With the exception for devoted exercisers, NEAT is the predominant component of activity thermogenesis. Not only that, NEAT is the most variable component of TDEE and varies by 200 kcal d^{-1} [37].

Perhaps some of the most carefully controlled studies examining the role of NEAT in weight gain have been performed by Levine et al. [35,38]. Levine found that resistance to the development of obesity may be caused by the ability of individuals to increase NEAT [35,38]. After 8 weeks of overfeeding (1000 kcal d^{-1}), participants who were able to increase NEAT gained the least fat mass. In contrast, those who failed to increase NEAT in response to overfeeding gained the most fat mass. Moreover, changes in basal metabolic rate and TEF did not predict changes in fat gain [35]. In a follow-up study, Levine and colleagues attempted to identify whether

there was a defect in NEAT in obese individuals. Using an integrated system of microsensors in undergarments to assess body posture and movements for 10 days, they found that obese individuals remained seated 2.5 hours longer than lean individuals, equivalent to an energy surplus of approximately 350 kcal d^{-1}. In other words, if the obese subjects were to adopt the same sitting pattern as their lean counterparts, they may expend an extra 350 kcal each day. Next, they examined whether weight loss in the obese participants and weight gain in the lean would reverse this usual pattern of posture allocation. Similar to previous studies [39], they showed that both the lean and obese groups maintained their original posture allocation suggesting that some of the interindividual variation in NEAT can be explained by a genetic component [38]. Taken together, these studies suggest that promoting NEAT in our daily environment may be significant but is unlikely to be a real target to manage weight control. Furthermore studies assessing the effects of interventions on NEAT require careful and accurate measurement of TDEE (usually by DLW) as well as assessment of the other components of TDEE (RMR and volitional physical activity).

Energy expenditure in the etiology of obesity

Cross-sectional studies that compare lean and obese individuals have added little to our understanding of the role of EE in the progression of obesity [40]. Understanding the pathogenesis of human obesity demands longitudinal studies to reveal predictors or risk factors. The Pima Indians living in south-western Arizona are one of the most obese populations in the world with the highest reported prevalence of type 2 diabetes [41] and provide opportunities to examine predictors of weight gain. Risk factors related to EE include low metabolic rate, low activity thermogenesis, low sympathetic nervous system activity, and low fat oxidation [40].

Low metabolic rate

Obesity is associated with a high absolute metabolic rate, both in resting conditions and over 24 hours and therefore was not thought to be a potential factor involved in the pathogenesis of weight gain and eventually of obesity. Whether a low energy metabolism is involved or not in the propensity to weight gain is, however, still controversial [42]. One of the reasons for this controversy may be related to the way EE is compared in people of different body sizes. It is obvious that RMR is higher in obese individuals in absolute terms, but when adjusted for differences in body size (i.e., RMR divided by body weight, surface area, FFM, or even adjusted for body size by multiple regression analysis), the results are not always clear. Indeed, there is wide variability in the association between metabolic rate and body size, such that two individuals with the same fat-free mass and fat mass can differ in metabolic rate by up to 500 kcal d^{-1} [43].

In 126 adult nondiabetic Pima Indians, body composition and metabolic rate (ventilated hood) was measured at baseline and follow-up 4 years later [44]. Using an arbitrary definition of weight gain of 10 kg, subjects were divided retrospectively into gainers ($n = 15$) and nongainers ($n = 111$). Despite the gainers and nongainers having similar body composition at baseline, the "weight gainers" had metabolic rates which were 100 kcal d^{-1} lower than the nongainers, suggesting that a low "relative" metabolic rate predicts weight gain. This was further supported by tertile analysis in the whole group, demonstrating that the risk of weight gain at follow-up was approximately seven times greater in subjects with the lowest metabolic rate compared to those with the highest metabolic rate [44]. In another group of 95 Pima Indians where 24-hour EE was measured in a metabolic chamber, 24hrEE adjusted for body size, age, and sex correlated negatively with the change in body weight and rate of change in body weight 2 years later [44], a relationship not found at all in other populations [45–47]. Taken together, these results demonstrate that low rates of EE (adjusted for body size, age, and sex), at least in populations more genetically susceptible to developing T2DM, are significant predictors of weight gain. Most interestingly, in response to weight gain, the mean adjusted metabolic rate of individuals who gained weight became similar to the mean adjusted metabolic rate of individuals who remained weight stable. This implies that weight gain may be a compensatory mechanism that results in an increased rate of EE engaging a mechanism of resistance to further weight gain (Figure 32.2). This "metabolic adaptation," defined as a greater than predicted increase in EE beyond changes in fat-mass and fat-free mass, is highly variable between individuals and occurs in both lean and obese individuals, Similarly, a reduction in EE in response to weight loss can counteract further weight loss or even predispose to weight regain [48]. Importantly, a low metabolic rate explains a relatively low percentage of the variance in weight gain, and therefore other factors such as excessive energy intake and reduced activity levels are likely culprits [49].

Low activity thermogenesis

The energy cost of exercise and nonexercise activity thermogenesis accounts for 10–20% of TDEE. The most variable component of activity thermogenesis is NEAT, also known as spontaneous physical activity (SPA) [39]. Using whole-room calorimetry, longitudinal studies in the Pima Indians demonstrated that SPA, defined as the percentage of time that subjects were active in the chamber, accounted for a significant portion of 24hEE in males and females [39]. Fifty-seven percent of the variance in SPA was related to family membership, that is, probably to genetic background. Furthermore, SPA correlated inversely with the rate of weight change assessed 3 years later in males [39]. It can be argued that the confined environment of a respiratory chamber may not reflect physical activity levels in free-living conditions. However, physical activity measured in a respiratory chamber correlated with habitual physical activity
Figure 32.2 Weight gain is the price to pay to counteract low energy expenditure or low fat oxidation. Cross-sectional studies consistently demonstrate a strong association between increasing energy expenditure and fat oxidation with increasing metabolic body size, but for any given body size, both parameters vary substantially. Longitudinal studies suggest that upon gaining weight, the low rates of energy expenditure and fat oxidation are increased on average and restored to normal levels and may oppose further weight gain. The arrows in the figure represent this metabolic drive toward weight gain, which probably diminishes at some point in some individuals, thereby limiting the amount of weight gain (metabolic adaptation, arrow A), whereas it may be sustained in others, who will thus be predisposed to further increases in weight (arrow B).

level assessed by doubly labeled water in 50 nondiabetic Pima Indians [50]. Several longitudinal studies have clearly demonstrated the association between reduced NEAT/SPA and weight gain [38,50]. Whether a similar association exists for habitual or structured physical activity is not clear [51–53]. A study in 92 nondiabetic Pima Indians showed that physical activity level (assessed by doubly labeled water) was not associated with changes in body weight 4 years later [49].

Low sympathetic nervous system activity

Reduced sympathetic nervous system activity (SNS) plays a causative role in several rodent models of obesity [54]. In humans, SNS activity can be directly measured in the muscle by microneurographic recordings [55]. This muscle sympathetic nervous activity (MSNA) correlates well with indirect measurements of SNS activity such as plasma norepinephrine turnover and plasma norepinephrine activity. In Caucasians, SNS activity is independently related to total daily EE [55,56] and to each of the major components of (TDEE- RMR) [55], TEF [57] and SPA [58]. However, such associations were not seen in Pima Indians [56], probably because Pima Indians have lower SNS activity compared to Caucasians [55]. Given that Pima Indians also have lower rates of total daily EE preceding weight gain [44] as well as reduced sympathetic nervous system activity, these two factors may represent potential mechanisms predisposing this population to body weight gain [55]. Indeed, baseline SNS activity (24-hour urinary epinephrine excretion rates) was negatively associated with weight gain after a 3-year follow-up [59]. Because the latter observation has not been

reported in other populations, the case for whether a reduced sympathetic nervous system activity precedes weight gain is still unclear.

Low fat oxidation

The choice of nutrient substrate (carbohydrate vs. fat) used for oxidation may be an important factor in the etiology of obesity and is calculated by the ratio between carbon dioxide production and oxygen consumption, the "nonprotein respiratory quotient (RQ)." RQ reflects the ratio of carbohydrate to fat oxidation and can vary between ∼0.7 after an overnight fast when fat is the primary substrate to values close to 1.0 after a high-carbohydrate meal when glucose is the principal energy substrate. Apart from the obvious influence from diet composition, other factors that may influence RQ are recent energy balance, sex, adiposity, and family membership, suggesting a genetic component to RQ [60]. Low fat oxidation has been suggested to be a factor in the development of obesity. In 111 Pima Indians, 24-h RQ (measured in a metabolic chamber) was correlated with subsequent changes in body weight and fat mass at follow-up 3 years later. In fact, subjects in the top 90th percentile of RQ ("low fat oxidizers") had 2.5 times greater risk of gaining 5 or more kilograms compared to individuals in the bottom 10th percentile of RQ ("high fat oxidizers") [60]. Similar results have also been reported in Caucasians [61].

Molecular mechanisms of energy expenditure variability and avenues for treatment

Leptin

Leptin, an hormone that is predominantly secreted by adipocytes and primarily binds to receptors in the hypothalamus as well as in the entire central nervous system, plays a key role in regulating long-term energy homeostasis in rodents and humans. Humans with the *ob* mutation lack circulating levels of leptin and therefore develop severe, early-onset obesity with associated metabolic and behavioral consequences including hyperphagia, defective thermogenesis, and T2DM. Leptin replacement therapy using daily subcutaneous injections completely reverses these symptoms in patients with congenital leptin deficiency as well as lipodystrophy, largely through the dramatic weight loss that occurs in these patients [62, 63]. These early findings in leptin-deficient patients suggested that administering leptin in obese patients would be a stand-alone magic bullet for the treatment of obesity. However, disappointingly this was short-lived. In 1999, a randomized control trial of daily subcutaneous recombinant leptin injection was performed in 54 lean and 73 obese subjects. In the initial phase of the study lasting 4 weeks, lean and obese subjects lost similar amounts of weight with leptin [64]. Obese subjects were studied for a further 20 weeks. Of the 47 patients who completed the study, the eight receiving the highest dose of leptin lost 7.1 kg while the placebo lost 1.3 kg. However, this weight change

varied widely among patients, from a loss of about 15 kg to a gain of 5 kg in the group treated with the highest dose. Moreover, these doses induced skin irritation and swelling at the injection site in 62% of patients and headache in half the patients. The potential of leptin therapy as a panacea for obesity appeared to be an early failure. However, leptin replacement therapy may be more pertinent for patients during weight loss maintenance. In calorie-restricted animals and humans, exogenous leptin administration has been shown to reverse the metabolic adaptation induced by caloric restriction and restore EE, catecholamine and thyroid hormone levels, and skeletal muscle efficiency back to baseline values [65, 66].

β3-adrenergic receptors

β3-adrenergic receptor (β3-AR) agonists are very effective thermogenic as anti-obesity and insulin-sensitizing agents in rodents with the main sites of action in skeletal muscle as well as white and brown adipocytes. Testing in humans with the first generation of β3-AR agonists, such as BRL 26830A and CL 316243, revealed promising results on energy metabolism. However, these compounds were not selective enough for the β3 receptor and shared substantial affinity for the β1- and β2-AR subtypes thus inducing many undesired effects such as accelerated heart rate, tremors, and hypokalemia [67]. The second generation of β3-ARs had improved selectivity but poor oral availability or pharmokinetics. Given these problems, we are not aware of any β3-ARs that have progressed beyond Phase II clinical trials [68]. However, given the recent findings that brown adipose tissue (BAT) is present in adult humans [69–71], the potential of β3-ARs agonists for increasing the amount and activity of BAT is an active area of exploration. Furthermore, a novel trend is now to target a subpopulation of adipocytes in the white adipose tissue to become more like brown adipocytes and therefore oxidize more fat.

Uncoupling proteins

The uncoupling proteins (UCPs) gene and especially UCP1 encode mitochondrial protein carriers, which uncouples respiration from ATP production stimulating heat production. Activation of such proteins may therefore be important for the control of metabolic efficiency. Discovered in 1978, UCP1, is only expressed in BAT and plays an important role in thermogenesis in rodents [72]. UCP1 was generally believed not to play a major role in energy balance as adults were thought to have very little BAT stores. However recent studies using 18^F-FDG labelled glucose in PET/CT revealed the presence of BAT in adult humans, the prevalence of which is estimated to be between 2 and 100% [69–71]. Currently, there is intense investigation into mechanisms for stimulating existing BAT or to induce BAT in white adipose tissue as a means to promote thermogenesis and EE [73].

In the late 1990s, two new mitochondrial uncoupling proteins were discovered, UCP2 (widely distributed in a variety of tissues) and UCP3 (abundantly expressed in skeletal muscle) stimulating great excitement into these new UCPs to explain

some of the variability in energy metabolism in humans. Transgenic mice with very high overexpression of UCP3 in their skeletal muscle were resistant to diet-induced obesity and had improved insulin sensitivity compared to their wild-type counterparts [74]. In humans, UCP2 and UCP3 expression levels were measured in skeletal muscle of 19 nondiabetic male Pima Indians covering a wide range of body weight. BMI was negatively associated with UCP3 expression, and metabolic rate during sleep, adjusted for fat-free mass and fat mass, was positively correlated with UCP3; no associations were observed between UCP2 and BMI or metabolic rate [75]. Whether UCPs play a significant role in the etiology of human obesity remains to be established.

Diacylglycerol transferase and acetyl CoA carboxylase

Triglyceride synthesis has been implicated to occur though the acyl CoA:diacylglycerol transferases (DGATs), enzymes that catalyze the final and only committed step in the glycerol phosphate pathway. DGAT1$^{-/-}$ mice are leaner than wild-type mice and have smaller adipocytes. When fed a high-fat diet, DGAT$^{-/-}$ mice are resistant to obesity and are protected from diet-induced hepatic steatosis likely due to increased EE. DGAT1$^{-/-}$ mice have increased spontaneous physical activity, increased expression of UCP1, and increased leptin sensitivity [76,77]. Conversely, overexpression of DGAT1 in adipose tissue results in impaired insulin sensitivity and liver steatosis [78]. These findings in rodent models where DGAT has been deleted suggest that pharmacologic inhibition of DGAT may be a novel therapeutic target for obesity in humans. Preclinical studies using DGAT inhibitors, such as T863, inhibits lipid absorption, causes weight loss, improves insulin resistance, and alleviates hepatic steatosis in high-fat-diet fed mice [79]. However, we are not aware of DGAT inhibitors in human clinical trials.

Acetyl CoA carboxylase

Acetyl CoA carboxylase (ACC), which exists in at least two isoforms in humans, is responsible for synthesizing malonyl coenzyme A, a potent inhibitor of fatty acid oxidation. ACC1 is expressed mainly in liver and adipose tissue, and ACC2 in the heart and skeletal muscle. Although mice lacking ACC1 die young, ACC2$^{-/-}$ mice have increased fat oxidation and therefore decreased weight and fat stores compared to wild-type mice. Furthermore, when exposed to a high-fat diet, ACC2$^{-/-}$ mice are resistant to obesity and the development of diabetes [80–84]. This preclinical evidence suggests that ACC inhibitors may serve as therapeutic targets for obesity and clinical trials are ongoing.

Analysis of energy expenditure data in humans

Regardless of the technique used to measure daily EE, adjustment for metabolic body size is essential for valid interpretation of the data. Traditionally, investigators have used the ratio method and simply divided EE by the amount of metabolic mass (body weight, fat-free mass, or surface area. However, this leads to erroneous results [85–87] since this method fails to take into account the nonzero intercept in the relationship between EE and metabolic mass. As a consequence, the adjusted metabolic rate is artificially increased as the fat-free mass decreases. An alternative and more valid approach is the regression-based approach which derives prediction equations from simple available measures (sex, age, FM, and FFM) to determine size-adjusted EE [85–87]. As one would expect, the method chosen for normalization of metabolic size is particularly crucial when assessing the effects of an intervention (weight loss, drug intervention, etc.) on EE.

Conclusions

The global obesity epidemic has stimulated intense interest in the genetic and molecular basis of body weight regulation. Changes in the components of energy expenditure, comprised of basal metabolic rate, thermic effect of food, and physical activity thermogenesis have important roles in energy balance. However, what ultimately determines "metabolic efficiency" is extremely complex. All components of energy expenditure are likely influenced by interactions between our individual genes and the environment affecting many physiological and biochemical processes. Recent progress in gene targeting and other technologies has pushed mouse models to the forefront of this effort. Whether these preclinical findings will translate into therapeutic utility for human obesity is not yet known. There is no doubt that the field of energy expenditure has developed tremendously over the years and understanding the homeostatic balance between energy intake and energy expenditure will continue to be an active research endeavor.

Treatment of obesity: lifestyle and pharmacotherapy

Arne Astrup

Department of Nutrition, Exercise and Sports, University of Copenhagen, Denmark

Key points

- Diet is the cornerstone in obesity management, and compliance to a reduced energy intake the challenge.
- Low-energy diets and very-low-energy diets using meal replacements are effective to induce weight loss by ensuring a high degree of adherence.
- A greater initial weight loss is associated with greater long-term retention and weight maintenance.
- Different diets take advantage of an enhanced satiety effect by higher protein content, and lower content of fat, refined carbohydrates, and sugar-rich soft drinks.
- Higher protein, low-carbohydrate diets are the most efficient and generally produce beneficial effects on all cardiometabolic risk factors.
- Weight loss in type 2 diabetics can be induced by diet and exercise. It has beneficial effects on glycemic control and reduces the use of antidiabetic medications.
- Weight loss in type 2 diabetics also improves QoL, sleep apnea, and cardiometabolic risk factors, but does not reduce cardiovascular events and mortality.
- Some antidiabetic medications have weight-neutral and weight-lowering properties.
- A number of weight loss medications have favorable effects on weight loss also in diabetics, and improve glycemic control and cardiometabolic risk factors.
- A number of new pharmaceutical compounds that target both obesity and type 2 diabetes are under development and show promise.

Introduction

Excess body fatness is the major environmental cause of type 2 diabetes (T2D), and even a minor weight loss can prevent its development in high-risk subjects. Weight loss and exercise programs can also improve quality of life, glycemic control, and comorbid conditions in type 2 diabetics, but do not reduce total or cardiovascular mortality. A weight loss of 5–10% can be induced in almost all simple and diabetic obese patients by a professional management program. Whereas the diet can be individualized, a higher protein, lower carbohydrate diet, with focus on low glycemic index carbohydrates, seems to be superior to a traditional low-fat diet for producing weight control and cardiometabolic risk improvement. Physical activity and regular exercise does not significantly affect rate of weight loss in the induction phase but plays an important role in the weight maintenance phase due to an important impact on daily energy expenditure and to direct enhancement of insulin sensitivity. Weight loss drugs have a role in patients in whom lifestyle treatment fails to produce the required weight control, and in obese subjects drugs may produce both weight loss and reduce the risk of complications, such as T2D.

Principles of diet-induced weight loss

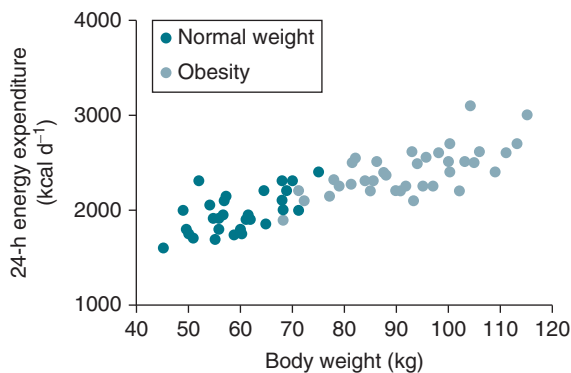
Dietary therapy consists of instructing patients on how to modify their dietary intake to achieve a decrease in energy intake whilst maintaining a nutritionally adequate diet and causing the fewest possible adverse effects on hunger and satiety. Obese patients have, due to their enlarged body size, higher energy requirements for a given level of physical activity than normal weight counterparts (Figure 33.1). Obese diabetics have slightly higher energy requirements than simple obese for a given body size and composition. Reducing the obese patient's total energy intake to that of a normal-weight individual will inevitably cause weight loss, consisting of about 75% fat and 25% lean tissue, until weight normalization occurs at new energy equilibrium. For patients with class I obesity this requires an energy deficit of 300–500 kcal d^{-1}, and for patients with class III obesity 500–1000 kcal d^{-1} until a satisfactory weight loss is achieved or an alternative approach is required.


Figure 33.1 Energy expenditure (energy requirements) of normal weight, overweight, and obese subjects. Relationship between body weight and energy requirements assessed by measurement of energy expenditure or by apparent energy intake during weight stability. The growing underreporting with increasing body fatness makes the self-reported energy intake invalid for estimation of energy requirements in obese patients.

There is no evidence that diet composition exerts clinically important effects on energy absorption and energy expenditure, but diet composition may affect hunger and satiety to such an extent that it facilitates reduction of total energy intake. Energy deficit can be achieved by setting an upper limit for energy intake. The larger the daily deficit in energy balance the more rapid the weight loss. A deficit of 300–500 kcal d^{-1} produces a weight loss of 300–500 g per week, and a deficit of 500–1000 kcal d^{-1} produces a weight loss of 500–1000 g per week. Greater initial energy deficits may produce even larger weight loss rates. Total energy expenditure declines and normalizes along with weight loss, and total energy intake must therefore be gradually further reduced to maintain the energy deficit. An alternative approach is to take advantage of the differences in the satiating power of the various dietary components in order to cause a spontaneous reduction in energy intake. This is the principle of ad libitum low-fat, low-carb, high-protein diets.

Choosing the dietary energy deficit

Initially the target of a weight loss program should be to decrease body weight by 10%. Once this is achieved a new target can be set. Patients will generally want to lose more weight and there is no evidence that unrealistically high weight loss expectations impair weight loss success [1], but it should be noted that even a 5% weight reduction improves risk factors and risk of comorbidities. However, several factors should be taken into consideration, including the patient's degree of obesity, previous weight loss attempts, medications, risk factors, comorbidities, and personal and social capacity to undertake the necessary lifestyle changes.

To prescribe a diet with a defined energy deficit it is necessary to estimate the patient's actual energy requirements. As assessment of the patient's habitual energy intake from self-reported diet registration is invalid as obese individuals systematically underreport energy intake by up to 30–40%. Energy requirements should therefore be assessed indirectly by estimation of total energy expenditure. Resting metabolic rate (RMR) can be measured by indirect calorimetry, or be estimated with great accuracy using equations based on body weight, gender, and age [2], or even better, estimated from the size of fat-free mass and fat mass. Total energy expenditure (=energy requirement) is estimated by multiplication of RMR (kcal d^{-1}) by an activity factor (PAL; physical activity level) [2]. The energy level of the prescribed diet is defined as the patient's energy requirement minus the prescribed daily energy deficit.

Theoretical versus clinical outcome

Translating physiologically based considerations regarding energy balance and weight loss into successful clinical practice requires a high degree of compliance on the part of the patient, which is difficult to obtain. Weight loss results tend to be much better in clinical trials conducted in specialized clinics than in trials conducted by nonspecialists without sufficient resources or access to auxiliary therapists (dieticians, psychologists, etc.). Compliance and adherence to the diet are the cornerstones of successful weight loss, and are the most complicated part of dietary treatment of obesity. To improve adherence the prescribed diet should match the patient's food preferences and food culture, and take personal, educational, and social factors into account. The patient must be seen frequently and regularly.

Long-term weight reduction is unlikely to succeed unless the patient acquires new eating and physical activity habits. These behavioral changes should be an integral part of the treatment program (see Chapter 41 on Behavioral Therapy).

Prognostic markers of weight loss success and reasons for failure

There is considerable variation in the weight loss and weight maintenance achieved by patients enrolled in dietary treatment programs. Some variation can be attributed to physiological differences (genes, resting metabolic rate, age, gender) and some to differences in adherence (genes related to adherence, behavior, acceptability of diet), although combinations of and interactions between physiology and behavior may be the major factor. This variation is not apparent from the mean weight loss of a group, which is difficult to translate into a clinically relevant success rate based on the intention to treat principle, that is, how large a proportion of the patients entering a treatment achieve a certain weight loss, typically >5% and >10% of pretreatment body weight. It is difficult to identify clinically the patients who will benefit most before treatment is initiated. The most powerful predictor of long-term weight loss success is initial weight loss, that is weight achieved within the first 1–2 months of treatment (Figure 33.2 (b)).

Options for weight loss diets

Therapeutic weight loss diets distinguish between several recognized regimens. Low-energy diets (LED) usually provide $800–1500\,\text{kcal}\,\text{d}^{-1}$, and use fat and carbohydrate-reduced foods. Very-low-energy diets (VLED) are modified fasts providing $200–800\,\text{kcal}\,\text{d}^{-1}$ that replace normal foods. Ad libitum low-fat diets do not restrict energy intake directly, but target a restriction of ad libitum fat intake to 20–30% of total energy intake. Energy intake is spontaneously reduced because of the higher satiating effect of this diet if protein intake is increased, and a modest weight loss occurs.

Very-low-energy diets (VLED)

Starvation (less than $200\,\text{kcal}\,\text{d}^{-1}$) is the ultimate dietary treatment of obesity, but it is no longer used because of the numerous and serious medical complications associated with prolonged starvation. Starvation has been replaced by VLED ($200–800\,\text{kcal}\,\text{d}^{-1}$), which aims to supply very little energy but all essential nutrients. Reducing the energy content of a diet requires an increased nutrient density. This can be difficult to obtain with natural foods if the diet is to be acceptable once the energy content is less than $800\,\text{kcal}\,\text{d}^{-1}$. This has led to the commercial production of VLED, supplemented with all nutrients in RDA amounts. For decades $250–400\,\text{kcal}\,\text{d}^{-1}$ formula diets were extremely popular. The first VLED were clearly nutritionally insufficient, but reports of adverse effects and results from research have brought about a gradual increase in energy level. Today the $800\,\text{kcal}\,\text{d}^{-1}$ VLED is the only version recognized as being both effective and safe. A number of studies have shown that VLED with energy levels of less than $800\,\text{kcal}\,\text{d}^{-1}$ do not produce a greater weight loss and are less well accepted than those comprising $800\,\text{kcal}\,\text{d}^{-1}$. VLED usually provide a ketogenic diet with an energy content of around $800\,\text{kcal}\,\text{d}^{-1}$ in the form of nutrition powders, or in the form of protein, mineral, trace element, and vitamin-enriched meals or drinks. VLED can induce very rapid weight loss over a 2–3 month period (Figure 33.2(a)), but should only be used as an induction of weight loss, and should be followed by a weight maintenance program. This is not because a rapid initial weight loss causes poorer long-term weight maintenance per se, as initial weight losses are positively associated with long-term weight loss [1]. Obese patients having the greatest initial weight loss during an 8-week $800\,\text{kcal}\,\text{d}^{-1}$ diet also retain the greatest weight loss during a subsequent maintenance program (Figure 33.2(b)).

VLEDs, compared with LEDs, induce significantly greater short-term weight losses, but similar long-term losses, and attrition has been found to be similar with VLED and LED regimens [4]. Some concern has been raised about the cardiac safety of the use of VLED with less than $\sim600\,\text{kcal}\,\text{d}^{-1}$ and patients using VLED have an increased risk of developing gallstones (Table 33.1). Their use without medical supervision has generally been abandoned and should not be recommended.

Low-energy diets (LED)

LED usually provide $800–1500\,\text{kcal}\,\text{d}^{-1}$ and normally consist of natural foods. LED are also called "conventional diets" or "calorie-counting diets" (because previously more emphasis was put on restricting the total energy level of the diet and less on the macronutrient composition). Although macronutrient composition of the diet is of less importance for short-term weight loss it is now usually modified in order to maximize the beneficial effect on cardiovascular risk factors and insulin resistance, and to prevent cancers, and perhaps also promote long-term weight maintenance. For practical reasons LED are low-fat, protein-rich diets with a fixed energy allowance. An example of an appropriate nutrient composition for an LED is given in Table 33.2. LED should be supplemented with a daily vitamin and mineral tablet. LED for women is $800–1200\,\text{kcal}\,\text{d}^{-1}$ and for men it is $1000–1500\,\text{kcal}\,\text{d}^{-1}$. LED produce a lower rate of weight loss than VLED, but randomized clinical trials (RCTs) demonstrate that the long-term (>1 year) weight loss is no different from that of the VLED [1]. Furthermore, using LED introduces healthy eating habits early in the weight reduction program, giving a longer period in which to familiarize the patient with the dietary changes that are a central element in a weight maintenance program.

Based on 34 RCTs examining the impact of LED in obese subjects it was concluded that LED produces weight loss regardless of duration of treatment, and body weight was reduced by an average of 8% over 3–12 months. In trials lasting 3–6 months, and 6–12 months, LED produced mean weight losses of approximately 8% compared to controls [5]. Though they targeted the same energy deficit there was a large variation in mean weight loss between studies. The variation is due less to differences in patient selection than to differences in the skill and efforts of the therapeutic teams. The same large variation exists within each cohort of patients and the mean weight loss of 8% corresponds to approximately 80% of the patients losing >5% and 15% losing >10%. It is difficult to separate the impact of the dietary therapy because all trials included some elements of behavior modification, which clearly contributed to the results.

Ad libitum lower fat diets (25–30% energy from fat)

Efficacy

Data from animal and experimental research, observational studies and numerous RCTs, have shown that a high dietary fat content plays some role in the development of obesity [6–8]. A high-fat diet especially promotes weight gain and obesity in sedentary individuals with little self-restraint. The main mechanisms are passive overconsumption of energy promoted by the high energy density of fatty foods, and a reduced fat oxidation capacity in susceptible individuals.

The lower fat diet (25–30% of energy) is clinically relevant for obese patients who habitually consume a high-fat diet (35–50% of energy), but for the majority of the obese population only a
Figure 33.2 (a) Distribution of weight loss in the 796 obese patients treated with 800 kcal d^{-1} total meal replacements for 8 weeks in the European multicenter trial Diogenes (Larsen et al. 2010). (b) Following the 8-week low-calorie diet they all went into a weight maintenance trial. This figure shows the 8 months weight loss outcome based on the 8-week weight loss quartiles, and demonstrate that the greater initial weight loss, the greater is the longer term success. Source: Handjieva-Darlenska 2011 [3]. Reproduced with permission of John Wiley & Sons.

modest reduction in dietary fat content is possible and more emphasis should be put on nonfat dietary components, such as reduction of soft drinks, and modification of protein, glycemic index, fiber, and whole grain, and on fat quality, in order to ensure the lowest cardiovascular risk profile.

Lower-fat diets can be more satiating provided the fat is replaced by protein and to some extent by low-glycemic index carbohydrates, high fiber foods, and whole grains. Low-fat diets where fat is replaced by refined starch and simple carbohydrates will produce little or no weight loss, and have adverse effects on cardiovascular risk factors.

A meta-analysis of 34 ad libitum, low-fat interventions lasting >2 months and 35 control groups, found a statistically highly significant weight loss difference of 3.3 kg [9].

Safety

A change from a normal-fat to a low-fat, high-carbohydrate diet has been shown to induce hyperinsulinemia, hypertriglyceridemia, and low HDL-cholesterol concentrations, but these effects are highly dependent on the composition of the nonfat part of the diet [10,11]. However, although healthier high-fat diets, that is, replacement of saturated and transfats with

Table 33.1 Adverse effects and complications of VLEDs

Adverse effect	Occurrence
Cold intolerance	~50%
Dry skin	~50%
Fatigue, dizziness, muscle cramps, headache, gastrointestinal distress	10–20%
Hair loss	10
Gallstones	10–30%
Bad breath	20–30%

Table 33.2 Example of the composition of an LED

Nutrient	Recommended intake
Calories	500–1000 kcal d^{-1} below energy requirements
Total fat	20–30% of total calories
Saturated fatty acid	<10% of total calories
Monounsaturated fatty acids	<15% of total calories
Polyunsaturated fatty acids	<10% of total calories
Protein	15–20% of total calories
Carbohydrate	>55% of total calories
Fiber	1000–1500 mg d^{-1}
Other vitamins, minerals, and trace elements	RDA. Full coverage should be ensured by a vitamin/mineral supplement daily

unsaturated oils instead of with carbohydrates, have proved to have beneficial effects on cardiovascular and diabetes risk profile, the higher energy density may increase risk of weight regain. Another example is the DASH-diet, a fat-reduced diet with increased intake of dairy products, fruit, and vegetables, that has been shown to produce a clinically relevant reduction in blood pressure, and other cardiovascular risk factors [12].

Low-carbohydrate, high-protein diets (HPLCDs)
Classification of high-protein, low-carb diets
There are a wide variety of popular diets and scientifically tested diets that are named either low-carb or high-protein diets (Atkin's, Dukan, The Zone, South Beach, I-diet, paleolithic diet), but they share the common feature that they are prescribed "ad libitum," that is, without energy restriction, and they work by suppression of hunger and enhanced satiety effect. They prescribe higher protein content either directly or indirectly through a marked restriction in total carbohydrate content, which automatically leads to higher protein content. They also stress carbohydrate quality, mostly by elimination of simple sugars, and either advocate carbohydrates with low glycemic index, high fiber and/or whole grain contents, and may achieve this by banning certain food groups that provide

starchy carbohydrates (e.g. paleolithic diet). There is no official classification but the increasing common definition is that a low-carbohydrate diet has ≤45% of energy from carbohydrates, low-fat diets have ≤30% of energy from fat, and high-protein diets have >20% of energy from protein. However, the protein content of high-protein diets can vary from 20–50% of energy, and there are numerous combinations of low-carb, high-protein diets that can be either low or high fat. A general scientific assessment is therefore subject to reservations and the imprecise classifications give rise to inconsistent outcomes of meta-analyses of efficacy and safety. It is also necessary to distinguish between diets consumed ad libitum and those with a fixed prescribed energy intake.

Efficacy of high-protein, lower carb diets
A large number of RCTs have been conducted to compare HPLCDs with low-fat diets, and a number of systematic reviews and meta-analyses have assessed efficacy and short-term safety. Approaches have varied slightly, but generally these analyses have found that HPLCDs have a more favorable effect on weight loss, body composition, resting metabolic rate, and cardiovascular risk factors than fat-reduced diets.

Santos et al. conducted a meta-analysis of 23 RCTs, involving 1141 obese nondiabetic subjects, on "low-carb" diets, based on a selection of publications that named the diet "low-carb" no matter the composition and degree of carbohydrate restriction [13]. They found that HPLCDs produced a 7.0 kg greater weight loss that low-fat diets over 6–12 months, and that the difference was maintained for up to 2 years. HPLCD caused greater reduction in waist circumference (−5.74 cm), systolic blood pressure (−4.81 mmHg), diastolic blood pressure (−3.10 mmHg), plasma triglycerides (−29.71 mg dL^{-1}), fasting plasma glucose (−1.05 mg dL^{-1}), glycated hemoglobin (−0.21%), plasma insulin, and in plasma hS-CRP, and an increase in HDL-cholesterol. No differences were found in LDL-cholesterol and serum creatinine levels.

Kreiger et al. used meta-regression of RCTs to determine the effect of changes in dietary protein and carbohydrate contents during energy restriction. They included a total of 87 studies, with 165 intervention groups, with diets providing at least 4200 kJ d^{-1} (1000 kcal d^{-1}). Diets that provided less that 35–41.4% energy from carbohydrate were associated with a 1.7 kg greater weight loss, a 0.7 kg greater loss of fat-free mass, and a 2.0 kg greater loss of fat mass than were diets with a higher percentage of energy from carbohydrate. In studies lasting more than 12 weeks the effects were increased to 6.6 kg weight loss and 5.6 kg greater fat loss. Protein intakes of more than 1.05 g kg^{-1} were associated with 0.60 kg additional fat-free mass retention compared to diets with protein intake of less than 1.05 g kg^{-1}. In studies with duration of more than 12 weeks this difference increased to 1.2 kg. Kreiger et al. concluded that HPLCDs favorably affect body mass and composition independent of energy intake, which in part supports the proposed metabolic advantage of these diets [14].

Wycherley et al. looked at the effects of isocaloric, high-protein versus normal protein diets with matched fat contents (normal to low) [15]. Twenty-four trials included 1063 individuals. Higher protein diets produced more favorable changes in body weight (0.8 kg), fat mass (0.9 kg), and triglycerides than normal protein diets, and mitigated reductions in fat-free mass and resting metabolic rate. Changes in fasting plasma glucose, fasting insulin, blood pressure, and LDL, HDL and total cholesterol, did not differ between diet types.

Finally, Hu et al. compared the effects of low-carbohydrate diets ($\leq$45% of energy from carbohydrates) with those of low-fat diets ($\leq$30% of energy from fat) in a meta-analysis of RCTs [16]. Twenty-three trials with a total of 2788 participants were analyzed. Both diets lowered body weight similarly and improved cardiometabolic risk factors. However, the low-carbohydrate diets produced a lower reduction in total cholesterol and LDL-cholesterol, a greater increase in HDL-cholesterol, and a greater decrease in triglycerides.

Mechanisms of action of high-protein, low-carb diets

From a physiological perspective there is evidence that any reduction of energy intake, whether it is achieved by prescribed energy reduction or by enhanced satiety on an ad libitum diet, should ensure a minimum protein supply in order to avoid excessive loss of lean body mass and subsequent reduction in metabolic rate. It is quite clear that the current RDA for protein is insufficient to avert adverse effects on body composition during weight loss, and that 2 × RDA, that is, 1.6 g protein per kg BW ($\sim$ at least 20% of energy from protein) is required [17]. A higher protein content also enhances satiety compared to carbohydrate, and some of the effects can be attributed to a stronger stimulation of gastrointestinal satiety hormones (GLP−1, PYY) [18]. Realistic protein contents are 20–35% of energy. A pronounced reduction of carbohydrate content enhances weight loss and improves cardiometabolic risk, but such a diet is difficult for many obese patients to adhere to in the longer term. A more realistic diet allows more carbohydrate, provided this is in the form of low-glycemic index carbohydrates. The weight-reducing effects of increasing the protein and of lowering the glycemic index of the diet are additive [19], and the low GI component enhances glycemic control [20] and decreases inflammation [21]. Moreover, this diet composition is more commensurate with Western food culture and is highly accepted among obese patients [22].

In conclusion, HPLCDs are more effective than low-fat diets at reducing weight and improving metabolic risk factors. Low-carbohydrate diets could be recommended to obese persons with abnormal metabolic risk factors for the purpose of weight loss.

Safety of high-protein, lower carb diets

If protein is increased in the diet from standard recommended levels of 10–15% of total energy to 25–30%, and fat is held constant at 30% of total energy, the percentage of carbohydrate consumed is reduced to 40–45% of total energy. The shift in the proportion of protein and carbohydrate in the diet should be achieved by replacing soft drinks containing refined sugar with high-protein beverages like milk, and adjusting the proportion of carbohydrate (i.e. smaller portions of white bread, rice, and pasta) and protein (i.e. larger portions of lean meat, fish, dairy products, beans, and lentils) during meals. These dietary changes will lead to a spontaneous reduction in total energy intake and body weight, and maintain the nutritional quality of the diet.

Unless lean protein sources are consumed, and intake of unrefined carbohydrate is maintained, high protein intake may result in reduced consumption of fiber, vitamins, and minerals (i.e. potassium, calcium, and magnesium), which could negatively impact cardiovascular, bone, and kidney function. Although these are reasonable possibilities, particularly for the Atkin's type diets with very low carbohydrate intakes, many studies suggest that replacement of some carbohydrate by protein has a neutral or even positive influence on inflammation, risk factors for T2D, bone health, and renal function [13,21,23–26].

Any assessment of HPLCDs' effects on cardiovascular risk factors needs to address the weight loss produced. Weight loss has such a powerful, beneficial effect on most risk factors, that the weight loss produced by HPLCDs can easily mask any adverse effect of the diet composition on risk factors. The effects on risk factors should therefore be studied when weight loss has plateaued.

RCTs of up to 2 years duration have not revealed any adverse effects on cardiometabolic risks. Contrastingly, a number of observational studies have found associations between HPLCDs and cardiovascular risks [13]. However, in these longitudinal studies relying on self-reported food intake, very few participants consumed a HPLCD and the prediction of risk was based mainly on statistical extrapolations from subjects consuming high amounts of protein, saturated fat, refined carbohydrates, and so on. These studies also found that consumption of HPLCDs is associated with weight gain, but it is difficult to see how these findings can be causally related in light of the lack of plausible, physiologic mechanisms.

Kidney and bone health

It has been suggested that very high protein intakes in animal studies may damage the healthy kidney, reduce GFR, and produce albuminuria. The few RCTs that have investigated this question in humans have not found any detrimental effect of high-protein diets, but rather the opposite [23–25,27], probably due to the fact that diabetes, hypertension, and obesity are risk factors of loss of kidney function, and as long as HPLCs produce weight loss all risk factors for impaired kidney function improve.

HPLCDs are beneficial for bone health in that they provide adequate protein, calcium, and vitamin D, during weight loss and maintenance [26,28].

Dietary weight maintenance programs

In professional weight loss programs LED induce a 5% weight loss in almost all patients, and frequent clinical encounters during the initial 6 months of weight reduction appear to facilitate achievement of therapy goals. More ambitious success criteria (>10% weight loss) can be met by the majority of patients if the treatment program also includes group therapy and behavior modification. A number of studies suggest that the use of IT-technology can further improve the cost-benefit of the programs. The real challenge is to maintain the reduced body weight and prevent subsequent relapse (Figure 33.3). In a systematic review of long-term (>3 years follow-up) efficacy of dietary treatment of obesity, success was defined as maintenance of all weight initially lost or maintenance of at least 9 kg of initial weight loss [29]. Initial weight loss was 4–28 kg and 15% of the followed-up patients fulfilled one of the success criteria, and the success rate was stable for up to 14 years of observation. Diet combined with group therapy led to better long-term success rates (27%) than did diet alone (15%), or diet combined with behavior modification and active follow-up, although active follow-up produced better weight maintenance than passive follow-up (19% vs. 10%).

Whereas energy restriction (LED) is successful for weight loss induction independent of dietary composition, the medium-fat, high-protein/low GI diet seems to be more effective for long-term weight maintenance and prevention of weight regain. Weight maintenance diets need to be realistic, unrestrictive, and to fit into a food culture in order to be accepted over the long term and achieve compliance from the reduced obese subjects.

In the Diogenes European multicenter trial the impact of higher protein and lower glycemic index of diets for prevention of weight regain was studied in 800 obese families. After an initial weight loss of 11 kg achieved by an 800 kcal d^{-1} diet over 8 weeks in the obese adults they were randomized to five diets differing in protein content and glycemic index. After 8 months

those randomized to higher protein and lower GI remained essentially weight stable, whereas those on diets with normal protein and higher GI regained weight [19]. The effect of higher protein (23% of energy) and lower GI was additive. This diet composition has also been shown to be effective in children [30], and to improve cardiometabolic risk [21]. The challenge is to incorporate the diet into a food culture in order to achieve long-term adherence.

Weight management programs for the prevention of type 2 diabetes

The potential of intensive lifestyle treatment to induce and maintain weight loss has been evaluated in two major studies on the prevention of T2D in obese subjects with IGT [31,32]. In the Finnish Diabetes Prevention study 522 overweight individuals with IGT were randomized to an intensive lifestyle intervention or to a control group [32]. The intervention aimed at a weight loss of >5% achieved by reduction of total dietary fat to <30% of calories from fat (<10% from saturated fat), >15 g per 1000 kcal fiber, and >30 min of exercise per day (walking, jogging, etc.). The subjects were instructed to eat whole grain products, vegetables, fruits, low-fat milk and meat products, and soft margarines frequently, and to avoid transfat and vegetables oils rich in mono-unsaturated fatty acids. Subjects attended seven counseling sessions with nutritionists during the first year of the intervention, and one session every 3 months in the subsequent years. The weight loss after 1 year was ∼5 kg, and after 5 years the weight loss maintained was still 3 kg. This intervention produced a 58% reduction in the incidence of T2D. In a subsequent analysis weight loss was the strongest predictor of the diabetes preventive effect, and a weight reduction of 5% was associated with a reduction in relative risk of 61%. Every 3 kg of additional weight loss doubled this effect. In the
Figure 33.3 Weight loss outcomes for obese patients treated in weight management programs compared to predicted outcome of continued habitual lifestyle. It is noted that even weight stability may be a partial success and a goal in certain patients.

much larger, but very similar, American Diabetes Prevention Program, 3234 obese individuals (mean BMI 34 kg m^{-2}) with IGT were randomized to intensive lifestyle, metformin, or a control group [31]. The goals of the lifestyle intervention were >7% weight loss, achieved by a diet providing <25% energy from fat and restricted to 1200–1800 kcal d^{-1}, and >150 min brisk walking per week [31]. The participants in the intervention group had 16 sessions with a nutritionist over the first 6 months, and subsequently one session per month for the remaining 2$^1/_2$ years. After 1 year the weight loss was 7%, and 5% was maintained throughout the trial as compared to the placebo group. The relative risk reduction of diabetes was the same as in the Finnish study—58% [31,32]. These studies strengthen the evidence that weight loss due to a combination of dietary intervention and physical activity is an effective strategy for diabetes prevention. Long-term follow-up of these studies show that a positive impact on diabetes risk and cardiovascular mortality is maintained even when the weight loss is not sustained.

Weight loss management in type 2 diabetes

Achieving and maintaining a desirable body weight is a major goal in management of T2D. Weight loss dramatically improves glycemic control, lipid profile, and blood pressure in obese individuals with T2D (ADA recommendations). For yet unknown reasons it is more difficult to produce and maintain weight loss in type 2 diabetics than in simple obese, but it is possible, and the health benefits are more substantial. In overweight and obese type 2 diabetics who have difficulty in losing weight on a conventional diet, a liquid-formula 800 kcal d^{-1} diet may be a safe alternative. Irrespective of whether an intensive 800 kcal d^{-1} diet consists of normal foods or of a liquid formula diet, weight loss after 3 months is 14–15% of initial body weight. This produces substantial improvements in glycemic control, blood lipids, and blood pressure. Most of the weight loss is maintained after 1 year. These studies show that it is possible to obtain substantial benefits in the treatment of type 2 diabetics through intensive diet therapy and lifestyle modification [27,33,34].

The large-scale Look AHEAD trial investigated whether intensive lifestyle intervention targeting weight loss in more than 5000 patients with T2D would reduce mortality over 13.5 years [33]. The study was discontinued because it was deemed unlikely to meet its primary objective, that is, to show survival benefits. Despite a rather modest weight loss the intervention very clearly demonstrated important quality of life benefits for participants, including improvement in HbA1c, but there was no reduction in hard cardiovascular end-points. However, the diabetic patients who lost weight benefitted from lowered HbA1c, reduced medications, increased physical fitness, less depression, as well as improved urinary incontinence, increased mobility, improved sleep apnea, and improved sexual function. Furthermore, participants who lost weight were more likely to experience remission of their T2D diabetes over the 4 years of the trial.

The lack of effect on CVD mortality may be attributed to the rather small weight loss of only 2.5% after 10 years, and the use of the traditional low-fat diet, of which any adverse effect on cardiovascular risk may have been masked by the weight loss.

Physical activity in type 2 diabetes
Physical activity alone may have a modest, but nevertheless important, effect on glycemic control. Favorable changes in glucose tolerance and insulin sensitivity usually deteriorate within 72 hours of the last exercise session. Consequently, regular physical activity is imperative to sustain glucose-lowering effects and improved insulin sensitivity.

According to a meta-analysis of intervention studies lasting >8 weeks addressing the effect of exercise on glycemic control and body weight in type 2 diabetics, aerobic and resistance training produced a beneficial effect on HbA1c of −0.66% but no effect on body weight [35]. However, training may reduce body fat and increase lean tissue mass, so that BMI is unchanged. Physical activity has other important beneficial effects in type 2 diabetics, such as on cardiovascular risk factors and general well-being.

Pharmacotherapy

Current licensed pharmacotherapies vary in different regions of the world. In the USA they include phentermine hydrochloride (phentermine HCl), a sympathomimetic appetite-suppressant approved for short-term (up to 12 weeks) treatment of obesity in conjunction with dietary and lifestyle modifications, and orlistat, a gastric and pancreatic lipase inhibitor globally approved for the long-term management of obesity. In addition, lorcaserin, a 5HT-2c agonist, and a once-daily slow-release combination of phentermine and topiramate, are both approved by the US Food and Drug Administration (FDA) for chronic weight management as an adjunct to lifestyle modifications in obese adult patients, and in overweight (BMI >27 kg m^{-2}) adult patients with at least one weight-related comorbidity. In Europe the European Medicines Agency (EMA) has only approved orlistat, and this compound is available in both a high-dose prescription version and in a low-dose over-the-counter version.

However, several other compounds, such as licensed antidiabetic medications with weight loss potential (acarbose, GLP−1 analogues, metformin) and compounds that are in phase III of development for the obesity indication, are relevant and the most important will be discussed briefly in this chapter.

Phentermine
Phentermine was approved by the FDA in 1959, and is the most commonly prescribed weight loss compound in the US [36]. It is only indicated for short-term treatment in patients with a BMI of >30 kg m^{-2} or >27 kg m^{-2} with obesity-related comorbidities (e.g. controlled hypertension, diabetes, dyslipidemia). Phentermine is a sympathomimetic related to amphetamine, and because of its abuse potential it is designated as a Schedule IV

controlled substance. Phentermine is administered orally, and the recommended daily dose is 15–37.5 mg in the morning, or one-half tablet two times daily. The dose should be individualized so that the lowest dose that produces a desirable weight loss is used.

Mechanism of action
Phentermine is an atypical amphetamine analogue that acts mainly by causing CNS release of norepinephrine (NE), thereby suppressing appetite and food intake. Phentermine shows only weak effects on dopamine and serotonin release, and is a weak uptake inhibitor of the serotonin transporter. Although increased NE release in the periphery may be perceived to increase the risk for adverse cardiovascular effects, NE released in CNS can act presynaptically to diminish sympathetic activity through a so-called clonidine-like effect [37]. This mechanism probably explains the finding that NE-uptake inhibitors (like sibutramine) paradoxically decrease sensitivity to sympathetic stimuli, such as stress and cold [37]. A slow-release phentermine preparation is also approved in the US for short-term treatment of obesity.

Efficacy
Phentermine has been evaluated in studies lasting up to 36 weeks, and a (30 mg d^{-1}) trial in overweight and obese women found weight loss of the order of 12–13 kg versus 4.8 kg in controls with both continuous and intermittent treatment regimens [38–40]. No long-term, randomized, placebo-controlled trial is available, but Hendricks et al. [41] found that patients treated with phentermine (15–37.5 mg d^{-1}) showed significantly greater weight loss over 2 years (12.7%) compared to a group on a low-carbohydrate ketogenic diet alone (8.4%). In a pooled analysis of studies lasting 2–24 weeks phentermine produced a 3.6 kg greater weight loss than placebo.

Adverse effects
The most common side effects are dry mouth and insomnia. Phentermine may be associated with cardiovascular complications, such as primary pulmonary hypertension, palpitations, tachycardia, increased blood pressure, and ischemic events, and is therefore contraindicated in patients with current or past cardiovascular disease, including uncontrolled hypertension. However, in patients in whom phentermine induces weight loss the treatment may actually lower blood pressure. Other contraindications are the same as those for monoamine oxidase inhibitors: hyperthyroidism, glaucoma, agitation states, pregnancy, or a known history of drug abuse. The abuse potential for phentermine is probably minor [42].

Phentermine/topiramate
Qsymia® (trade name in the USA) is a combination product for oral administration of immediate-release phentermine and extended-release topiramate licensed in the US as an adjunct to a reduced-calorie diet and increased physical activity for chronic weight management in obese patients (BMI ≥30 kg m^{-2}), or overweight patients (BMI ≥27 kg m^{-2}) with weight-related comorbidities such as hypertension, T2D, dyslipidemia, or central adiposity (abdominal obesity).

Mechanism of action
Phentermine mediates norepinepherine release in the CNS, and thereby induces weight loss by reducing food intake (see earlier). Topiramate exhibits a combination of properties that involves modulatory effects on sodium channels, enhancement of GABA-activated chloride channels, inhibition of excitatory neurotransmission through actions on kainite and AMPA receptors, and inhibition of carbonic anhydrase isoenzymes, but its precise mechanism of action to reduce food intake is not known. Topiramate was approved in 1996 for the treatment of seizures at doses up to 400 mg d^{-1}, in 2004 for the prevention of migraine headaches at doses up to 100 mg d^{-1}. Topiramate was initially also developed for the weight loss indication with 96 or 192 mg d^{-1}, and demonstrated long-term weight loss efficacy, but the program was stopped due to tolerability issues, that is, cognitive and speech disorders, and paresthesia [43]. The combination of phentermine and topiramate was developed for obesity management in three dosages taken once in the morning: low-dose (3.75 mg P/23 mg T), mid-dose (7.5 mg P/46 mg T), and high-dose (15 mg P/92 mg T), and the weight loss effects of its two components seems to be at least additive. It is recommended that doctors prescribing Qsymia follow a treatment algorithm: they should start with the low dose daily for 14 days; then increase to the mid dose, and then discontinue or escalate dose if 3% weight loss is not achieved after 12 weeks on this dose. They are also advised to discontinue Qsymia if 5% weight loss is not achieved after 12 weeks on maximum daily dose of 15 mg/92 mg. Discontinue 15 mg/92 mg dose gradually (as described) to prevent possible seizure. Do not exceed 7.5 mg/46 mg dose for patients with moderate or severe renal impairment or patients with moderate hepatic impairment.

Efficacy
The amount of weight loss achieved with combination therapy is of a greater magnitude than what could be achieved with either agent alone [43–47]. Data from phase 3 studies indicate that Qsymia produces significant weight loss in conjunction with improvements in obesity-related comorbidities such as hypertension, diabetes, and dyslipidemia. The three-dose regimens produce weight loss that is about 3, 7, and 9 kg greater than placebo plus diet and exercise program in 1-year trials (Figure 33.4). The corresponding weight loss in type 2 diabetics was ~7 kg [47]. In pooled analyses, Qsymia produced greater reductions in waist circumference, LDL-C, HbA1c, and SBP and DBP than placebo, and improvements in HDL-C compared to placebo. In pooled data of hypertensive subjects from the two 1-year studies, significant reductions in SBP (~9 mmHg) and DBP (~5 mmHg) were seen in all Qsymia groups, while heart rate was slightly increased in the 15/92 dose group (~2 bpm).
Figure 33.4 Phentermin/topiramate for the treatment of obesity. Weight loss from baseline to week 56 (1-year studies; ITT-LOCF) in overweight and obese adults and in adults with type 2 diabetes treated with a combination of low-dose phentermine and topiramate extended-release as an adjunct to lifestyle intervention for the. *$p < 0.0001$ vs. placebo.

A large-scale cardiovascular hard endpoint study is ongoing. The primary endpoint will be the time from randomization to a nonfatal myocardial infarction, nonfatal stroke, or cardiovascular death.

Adverse effects

Several of the most commonly observed adverse events, occurring in 5% or more of study subjects, included paresthesia, dizziness, dysgeusia, insomnia, constipation, and dry mouth. Slight increase in heart rate, psychiatric and cognitive adverse effects, and metabolic acidosis are potential safety concerns. While the overall incidence rates are low, about 4–7 times as many subjects randomized to high-dose Qsymia versus placebo discontinued study participation due to anxiety-, sleep-, and depression-related adverse events. However, these effects are well-known and characterized side effects of one or the other component agent and do not represent novel side effects engendered through the combined pharmacology of the two drugs. There is no evidence of any new or unexpected safety issues with the combination relative to phentermine or topiramate monotherapy.

Lipase inhibitors (orlistat)

Mechanism of action

Malabsorption of dietary fat is an obvious drug target, and a number of compounds that act as intestinal lipase inhibitors have been investigated for use in the treatment of obesity, but only orlistat is currently approved and freely available. Orlistat is a specific inhibitor of intestinal lipase, the enzyme secreted from the exocrine pancreas and responsible for enzymatic fat digestion [48,49]. Orlistat inhibits lipase activity through formation of a covalent bond with serine within the catalytic site of gastric and pancreatic lipase. Orlistat is available on prescription at a recommended therapeutic dose (120 mg), and as an over-the-counter half-dose preparation (60 mg), both taken immediately prior to or within 1 hour of each of the 3 main daily meals. Fecal energy loss is not fully compensated by an increased caloric intake so orlistat produces a negative energy balance and weight loss. Orlistat is recommended for use as pharmacologic support for a nutritional strategy of a modest caloric restriction and a diet providing less than 30% of energy from fat. An obese patient with a typical energy requirement of 2600 kcal d^{-1} will, on a 600 kcal deficit diet with 30% of calories from fat, experience an extra loss of 220 kcal fat in fecal energy.

Efficacy

The efficacy and safety of orlistat have been documented in several short- and long-term double-blind trials, some lasting for up to 4 years, involving a total of almost 30,000 patients, making orlistat the most well-investigated drug for the treatment of obesity. In most trials orlistat induces a dose-dependent

reduction in body weight, and the 120 mg dose induces a mean weight loss that typically exceeds that seen in the placebo group by 3–4 kg, to some extent independent of the degree of dietary energy restriction and other ancillary treatment. The weight loss typically continues for the first 3–6 months of treatment and then plateaus and patients may subsequently remain weight stable or regain some weight depending on the intensity of the dietary treatment. In obese subjects with the metabolic syndrome (insulin resistance syndrome) orlistat produces weight loss of the same magnitude as in simple obese, and the weight loss is associated with significant decreases in fasting insulin, triglycerides, the LDL/HDL cholesterol ratio and increase in HDL-cholesterol [50].

Use in prediabetes

Treatment of obese subjects with IGT by orlistat as an adjuvant to diet and lifestyle modification has been shown to decrease the rate of conversion to T2D. In a multicenter trial 3304 nondiabetic obese subjects underwent intensive lifestyle modification with a dietary energy deficit of 800 kcal d^{-1}, and were randomized to either orlistat or placebo for 4 years [51]. The mean weight loss was greater by 4 kg in the orlistat group after 1 year, and most of this weight loss was maintained throughout the rest of the study period. Weight loss was 6.9 kg in the orlistat group and 4.1 kg in the placebo group after 4 years. Nine percent in the placebo group but only 6.2% in the orlistat group had developed T2D after 4 years (relative RR = 37%). In addition, orlistat patients obtained greater reductions in waist circumference, LDL cholesterol, and systolic and diastolic blood pressures than placebo patients. The study clearly shows that the additional weight loss achieved by orlistat is sufficient to reduce the incidence of diabetes, even among more nonselected obese subjects where 80% had normal glucose tolerance. In the 20% of patients with IGT at enrollment the intensive lifestyle change alone resulted in a similar absolute diabetes incidence as the lifestyle treatment in the Diabetes Prevention Program [31].

Use in diabetics

One-year multicenter trials have been conducted with the use of orlistat in addition to each of the treatments of T2D: sulfonylurea, insulin, and metformin. Whatever medication the diabetics received at baseline, orlistat produced weight loss above diet and placebo of 2–5 kg [48], reductions in HbA1c of 0.46% (sulfonylurea), 0.35% (insulin) [52,53], and 0.29% (metformin). Greater reductions were also seen in LDL-cholesterol and blood pressure in the orlistat groups.

Adverse effects

Systemic absorption of orlistat and its metabolites is negligible, so adverse effects of orlistat are a consequence of the partial reduction of fat absorption, leading to an increased proportion of undigested fat in the bowel. The most frequent adverse effects of orlistat are flatulence, flatulence with discharge, oily spotting, fecal urgency and incontinence, oily stools, and steatorrhea.

In most patients these adverse effects are self-limiting and mostly transient, generally occurring within the first months of treatment and often triggered by the ingestion of high-fat meals. However, the adverse effects tend to limit its use in many patients.

The unabsorbed fat binds some fat soluble vitamins (A, D, and E) and secondary nutrients (beta-carotene, lycopen, flavanoids, etc.). A simple vitamin supplement and increased intake of fruit and vegetables counteracts this effect. Pharmacodynamic studies suggest that orlistat does not affect the pharmacokinetic properties of lipid-soluble drugs such as digoxin, phenytoin, warfarin, glyburide, furosemide, captopril, nifedipine, atenolol, or oral contraceptives [54].

Lorcaserin

Mechanism of action

Lorcaserin is a selective serotonin 2C (5-HT$_{2C}$) receptor agonist that is intended for weight reduction and weight maintenance in obese patients, or overweight patients (BMI $\geq 27–30$ kg m^{-2}) who have one or more weight-related comorbid medical conditions [55–57]. Serotonin was found to decrease food intake and reduce body weight in animals 50 years ago, and these effects are mediated in part through activation of centrally located 5-HT$_{2C}$ receptors. The historical weight control agents fenfluramine and dexfenfluramine, however, lacked specificity; each enhanced serotonin release and blocked its reuptake, leading to nonselective activation of multiple serotonin receptor subtypes [58]. As a result, fenfluramine caused serious adverse events that included heart valve vegetations that led to echocardiographically apparent aortic and mitral valve insufficiency. Serotonin valvulopathy appears to be mediated through activation of serotonin 2B (5-HT$_{2B}$) receptors located in the heart, whereas lorcaserin predominantly activates 5-HT$_{2C}$ receptors without significant agonism of the 5-HT$_{2B}$ receptor at therapeutic doses. The agonist activity of lorcaserin at the 5-HT$_{2A}$ receptor, which has been linked to mood and perceptual effects, is minimal. Given that 5-HT$_{2C}$ receptor expression is primarily limited to a few regions of the central nervous system, lorcaserin should cause weight loss with few unintended pharmacologic effects.

Efficacy

Lorcaserin caused significant, dose-dependent weight loss in obese patients and overweight patients with at least one weight-related comorbid condition. Nondiabetic patients treated with lorcaserin 10 mg BID lost 5.8 kg over 1 year as compared to 2.5 kg in the placebo group [59]. A meta-analysis found weight loss of 3.2 kg (95% CI 2.7–3.8) greater than with placebo in trials of 1-year duration [60]. The use of lorcaserin for 8 and 12 weeks reduced weight by 1.6 kg and 2.9 kg, respectively. Of patients treated with lorcaserin 10 mg 47.1% achieved $\geq$5% reduction in body weight after 52 weeks as compared to 22.6% of patients treated with placebo, and 22.4% of patients treated with lorcaserin achieved $\geq$10% weight loss as compared to 8.7% in the placebo group.

In comparison to placebo, lorcaserin decreased waist circumference, blood pressure, total cholesterol, LDL-cholesterol and triglycerides; however, it did not statistically affect heart rate or HDL-cholesterol [56], and also produced positive effects on glycemic control and insulin resistance, inflammatory markers, and quality of life in trials of 1-year duration, and many of these effects were maintained in year 2.

In patients with T2D lorcaserin produced a weight loss of 4.7 kg as compared to 1.6 kg in the placebo group, and it improved glycemic control relative to placebo and reduced the use of antihyperglycemic medications. Over half of patients taking lorcaserin achieved the ADA recommended glycemic goal of HbA1c $\leq$7% compared to 26% in the placebo group.

Adverse effects

The most frequent adverse effect is headache, but also dizziness, nausea, fatigue, urinary tract infections, dry mouth, and back pain are frequent side effects of lorcaserin. The majority of headache, dizziness and nausea effects occur early on in the course of treatment, tend to be mild to moderate, and generally do not recur after resolution of the initial event. In type 2 diabetics hypoglycemia is the most frequently reported adverse event. Though lorcaserin has been associated with excess neoplasia or with evidence of hepatic toxicity in some rodent studies, there has been no evidence of this in humans. Lorcaserin does not cause clinically significant increases in serum prolactin, nor does it appear to increase the risk of cardiac valvular disease. Lorcaserin should not be used in patients with creatinine clearance $\leq$30 mL min^{-1}.

Pharmaceutical compounds for diabetes treatment with weight loss properties

Metformin

Metformin is a biguanide that is approved for the treatment of T2D. It lowers plasma glucose by reducing intestinal absorption, suppressing hepatic glucose production, and increasing peripheral insulin sensitivity. It has long been known to induce a slight weight loss not only in diabetics but also in obese subjects with metabolic syndrome or IGT. The size of the placebo-subtracted weight loss induced by metformin in diabetics varies from 0.5 kg to 8 kg, probably depending on BMI, age, and glycemic control [53]. In the Diabetes Prevention Program of obese subjects with IGT, metformin produced a 2.0 kg weight loss and reduced the incidence of diabetes by 31% above placebo after 3 years [31]. A subgroup analysis revealed no difference in efficacy across gender and ethnicity, but the effect was mainly seen in subjects aged 25–59 years with a BMI above 30 kg m^{-2}, whereas it was largely ineffective in nonobese (BMI < 30 kg m^{-2}) and those older than 60 [31]. In this trial more than 1000 patients entered each treatment arm and the resulting high statistical power gives more credit to the outcome than those of smaller trials.

Metformin may produce weight loss through effects on AMPK and mitochondrial function, and the improvement in insulin sensitivity may increase the central effect of insulin where it acts as a satiety hormone. Another possibility is that reduced food intake is caused by nausea and other gastrointestinal effects. There are no indications of any thermogenic effect of metformin.

Amylase inhibitors (acarbose)

Inhibition of digestion of starch and disaccharides reduces absorption of di- and monosaccharides and produces a reduction in blood glucose and a negative energy balance, providing that energy intake is not increased by counterregulatory mechanisms. Acarbose is an antidiabetic drug that lowers blood glucose by inhibition of α-glucosidase in the gastrointestinal tract, thereby delaying the hydrolysis of ingested disaccharides and complex carbohydrates. Theoretically, efficacy with respect to body weight regulation is modest, as starch that is not digested in the small intestine is fermented in the colon and finally absorbed as short chain fatty acids. It is estimated that fermentation of carbohydrates in the colon is associated with a 50% reduction of energy content available for the body, thus reducing the energetic value of carbohydrates from 4 to 2 kcal g^{-1}.

However, the effect of acarbose on glycemic control in diabetics is modest, and the effect on body weight is negligible in simple obese [61], obese with IGT [62], and in type 2 diabetics [63]. In a weight maintenance study in simple obese subjects Hauner et al. failed to find any effect on body weight of 6 months acarbose treatment following an initial diet-induced weight loss of 10 kg [61]. Three years of acarbose treatment produced a weight loss of 0.8 kg compared to placebo, and the risk of progression to diabetes over 3.3 years was reduced by 25%, which could be attributed mainly to the weight loss [62]. However, 31% of the patients in the acarbose group, compared to 19% in placebo group, discontinued treatment early, mainly due to gastrointestinal side effects [62]. About 50% more patients reported side effects on acarbose than on placebo, mainly flatulence, abdominal pain, and diarrhea. The effects of acarbose in T2D are equally unpromising. In the UKPDS, 1946 type 2 diabetics randomized to acarbose or placebo were followed for 3 years [63]. Fifty-eight percent of the patients discontinued acarbose versus 39% drop-out in the placebo group. In an intention-to-treat analysis acarbose produced only a 0.2% lower HbA1c than placebo, while in those who remained on the allocated therapy the HbA1c was 0.5% lower. Mean body weight was lower by 0.4 kg in the acarbose group after 1 year, but no difference was seen after 2 or 3 years [62].

In conclusion, acarbose produces only a very modest (<1 kg), if any, weight loss and, taken together with its low tolerability due to prevalent gastrointestinal side effects, has no place in the treatment of obesity. Acarbose may, however, have some role in type 2 diabetics with a capacity to tolerate the compound [63].

GLP−1 analogues

The GLP−1 analogues exenatide (two injections per day or long-acting release form once weekly) and liraglutide (one injection per day) are licensed for the treatment of T2D, and more are under investigation (albiglutide, taspoglutide, lixisenatide [64] and more). Some of these analogues are being developed for both diabetes and obesity indications [65].

Mechanism of action

The first evidence that GLP−1 is a hormone responsible for inducing postprandial satiety and reduced spontaneous caloric intake in normal humans was published in 1998 [66]. It was also found that obese individuals require higher doses than normal weight individuals to achieve the same degree of satiety, and that the satiety effect requires higher dosages than those required to obtain glucose lowering. Native GLP−1 has a very short half-life but development of analogues has enabled treatment with injections producing supraphysiologic plasma levels. Exenatide, for TID, and liraglutide once daily, are both licensed for the management of T2D as they produce a clinically relevant reduction in HgbA1c. Because the satiety action of GLP−1 is further stimulated by higher doses than the glucose-lowering effect, current doses of exenatide and liraglutide (i.e., 1.2 and 1.8 mg d^{-1}) used in T2D are not optimal for weight loss.

Efficacy

The weight loss in type 2 diabetics in RCTs of GLP−1 agonists is typically only 1–3 kg greater than placebo over 6 to 12 months, with no difference between short- or long-acting agents, or between exenatide and liraglutide. Liraglutide has been assessed in a number of long-term trials in nondiabetic obese populations at doses up to 3.0 mg d^{-1}. Astrup et al. reported a dose-finding study with different doses of liraglutide versus placebo and versus orlistat in obese subjects treated with a mild hypocaloric diet over 24 weeks [67]. Liraglutide produced a dose-related weight reduction that was greater than placebo for all doses from 1.2 to 3.0 mg d^{-1}, with a clear separation of dosages. Liraglutide 3.0 mg produced mean weight loss 4.4 kg greater than placebo, and 3.1 kg greater than orlistat. This trial was extended to 1 year, and subsequently all liraglutide and placebo patients switched to liraglutide 2.4 mg, then to 3.0 mg [68]. From randomization to year 1 liraglutide 3.0 mg recipients lost 5.8 kg (3.7–8.0) more weight than those on placebo, and 3.8 kg (1.6–6.0) more than those on orlistat (Figure 33.5). In the SCALE program a number of trials have extended the efficacy of 3 mg liraglutide in nondiabetic obese patients, and placebo-adjusted long-term weight loss has been in the order of 5–7 kg.

Liraglutide exerts beneficial effects on almost all clinically relevant cardiovascular risk factors, that is, blood pressure, blood
Figure 33.5 Two-year weight loss effects of the GLP−1 agonist liraglutide. Change in body weight from screening over 2 years, presented as observed data for individuals completing each scheduled visit. A randomized, double-blind, placebo-controlled 20-week study with 2-year extension in 564 obese patients. Participants received diet (500 kcal deficit per day) and exercise counseling during 2-week run-in, before being randomly assigned to once-daily subcutaneous liraglutide (1.2, 1.8, 2.4, or 3.0 mg), placebo, or open-label orlistat (120 mg × 3). After 1 year, liraglutide/placebo recipients switched to liraglutide 2.4 mg, then 3.0 mg. At year 2, participants on liraglutide 2.4/3.0 mg for the full 2 years lost 3.0 kg more weight than those on orlistat. Completers on liraglutide 2.4/3.0 mg maintained a 2-year weight loss of 7.8 kg from screening. Source: Astrup et al. 2012 [68]. Reproduced with permission of Nature Publishing Group.

lipids, inflammatory markers, and glucose metabolism in non-diabetic obese patients. In the trial by Astrup et al. 31% of the obese patients had prediabetes at randomization, and 41% met the criteria for metabolic syndrome. Between 52–62% of the liraglutide-treated individuals with prediabetes at randomization achieved normal glucose tolerance at year 2, compared with 26% of those on orlistat.

Safety of GLP−1 analogues

The most frequent side effects are mild to moderate transient nausea and vomiting. These side effects are clearly dose-related, and it is likely that individual differences in sensitivity to GLP−1 are responsible, so that increasing receptor stimulation may be responsible for moving from enhanced satiety to nausea. This interpretation is supported by findings showing that weight loss with liraglutide 3.0 mg at 1 year from randomization was 10.0 kg for those with nausea and/or vomiting, and 7.1 kg for those without (difference 2.9 kg $(0.5–5.3, p < 0.02)$). In the Astrup et al. trial 53% of patients taking liraglutide 3.0 mg reported nausea compared to 8% in the placebo group and 7% in the orlistat group [68]. Most nausea/vomiting episodes started in the first 6 weeks of treatment, were transient, and were of mild or moderate intensity. Few episodes were serious. Another cardiovascular side effect is an increase of 1–4 bpm after 1 year intervention. This is presumably caused by a direct stimulation of the sinus node of the heart.

Patients with T2D have a 2.8-fold, and obese subjects a 2.2-fold, higher risk of developing pancreatitis than the general population [69,70]. A possible mechanism for some of the cases of pancreatitis observed in the trials may be the triggering of acute pancreatitis among susceptible individuals, such as obese and type 2 diabetic subjects, by weight-loss induced gallstones. A recent meta-analysis concluded that there is no evidence to support an increased risk of acute pancreatitis associated with the use of GLP−1 agonists [71] but we are still waiting for the outcome of some of the long-term outcome studies like LEADER, ELIXA, and others before this potential side effect can be quantified.

Other pharmacologic agents under development

Bupropion/naltrexone
Mechanism of action

Bupropion and naltrexone were approved for other indications in 1984–85, but both have been associated with weight loss. Bupropion stimulates hypothalamic pro-opiomelanocortin (POMC) neurons, with downstream effects to reduce food intake and increase energy expenditure. Naltrexone blocks opioid receptor-mediated POMC autoinhibition, augmenting POMC firing in a synergistic manner. Given the fact that both drugs have effects on addiction, alcohol and nicotine, respectively, the combination was considered to induce weight loss through sustained modulation of CNS rewarding pathways [72].

Efficacy

A number of trials with the sustained release combination of naltrexone and bupropion, in combination with mild diet and exercise in overweight and obese subjects, have shown good efficacy in terms of weight loss as the combination produced a weight loss around 4–5% greater than placebo [73,74]. Bupropion is associated with a slight increase in blood pressure and heart rate, whilst the phase III trials on the combination have found unchanged heart rate and blood pressure despite the reduction in body weight.

Adverse effects

Bupropion is generally considered a reasonably safe medication for smoking cessation. However, 30–40% of treated patients may suffer from insomnia, and generalized seizures occur in approximately 0.4%. Other side effects are agitation and anxiety [74]. Naltrexone has been associated with adverse events such as difficulty in sleeping, anxiety, nervousness, and headache.

The most frequently reported treatment-emergent adverse events for the combination compound are nausea, insomnia, headache, and constipation, but no tendencies to worsening of various anxiety, depression, or suicidal sub-scale scores have been found, nor were there more adverse events or withdrawals due to these psychiatric conditions. These findings suggest that the combination may have fewer adverse psychiatric effects than its components given separately.

CHAPTER 34

Treatment of obesity: bariatric surgery

Karl J. Neff[1], Ele Ferrannini[2] and Carel W. le Roux[1]

---

Key points

- Bariatric surgery is the most effective treatment for obesity.
- In addition to weight loss, bariatric surgery has significant effects on metabolic disease, and particularly diabetes.
- These surgical procedures should now be considered as treatments for metabolic disease, to be added to medical therapy in selected cohorts.
- There are multiple potential mechanisms underlying weight loss and improved glucose homeostasis after each procedure, which likely act in concert.

Introduction

The primary focus of bariatric surgery since its introduction has been the reduction of body weight [1–3]. However, as well as sustained effects on weight loss, bariatric surgery is associated with improvements in several obesity-related conditions, from airway diseases to cancer [1,2,4]. Despite increasing evidence of benefit for obesity-associated diseases, the major national guidelines in the United States and Europe for selecting candidates for bariatric surgery continue to focus on body mass index (BMI) as a primary indication, and outcomes are based on changes in weight. This standpoint is changing, and the potential benefits of bariatric surgery beyond that of weight loss are beginning to be appreciated.

In metabolic disease, bariatric surgery results in marked improvements in glycemic control in type 2 diabetes mellitus (T2DM). In some patients, remission of diabetes, hypertension, and dyslipidemia can be achieved within weeks, and in the case of diabetes this can be before the onset of significant weight loss [5]. However, the definition of remission of these metabolic disorders has varied in the past, in the absence of a consensus on how this term should be defined. In most studies, remission is defined by clinical report rather than objective examination or biochemical analysis. The discontinuation of pharmacologic therapy for metabolic disorders has also been used as a surrogate for remission. This means that these studies should be interpreted with some degree of caution.

Findings from randomized controlled trials have demonstrated that bariatric surgery is superior to best medical care alone for obesity-associated T2DM [6,7]. Bariatric surgery improves glycemic control for up to two years in randomized controlled data, but also reduces mortality and maintains adequate control of diabetes for at least 10 years in observational data [1,2,6,7]. The remit of surgery is now beyond that of weight control or reduction, and surgery could be considered a useful therapy in more patients with metabolic disease or dysfunction.

Current surgical approaches

The most commonly performed bariatric procedures are Roux-en-Y gastric bypass (RYGB), adjustable gastric banding (AGB), and vertical sleeve gastrectomy (VSG) [8]. Biliopancreatic diversion with or without duodenal switch (BPD, BPD-DS) is less commonly performed [9]. All procedures can be performed laparoscopically with a low rate of complications such as wound infection and incisional hernias [10].

RYGB involves the division of the stomach into an upper gastric pouch, which is ∼30 mL in volume, and a lower gastric remnant (Figure 34.1(a)). The gastric pouch is anastomosed to the jejunum after it has been divided some 30–75 cm distal to the ligament of Treitz; this distal part is brought up as a "Roux limb." The excluded biliary limb including the gastric remnant is connected to the bowel some 75–150 cm distal to the gastrojejunostomy (Figure 34.1(b)).

AGB, vertical banded gastroplasty (VBG), and VSG have a surgical focus on the stomach, with either a partial gastrectomy (VSG) or gastric restriction by means of bands (AGB) or stapling of a portion of the stomach (VBG). Despite this focus,
---

(a) (b)

Figure 34.1 (a) Roux-en-Y gastric bypass: the length of the alimentary and biliopancreatic limbs can vary, but the basic design of this procedure results in nutrients moving directly from gastric pouch to post-duodenum small intestine. The relative importance of the effects of duodenal exclusion and increased nutrient exposure to the ileum remains a matter of debate and a focus of much research. (b) Roux-en-Y gastric bypass: the volume of the gastric pouch formed in this procedure can vary. (For a color version of this figure, please see the color plate section.)

in AGB a silastic band is applied around the stomach just below the gastroesophageal junction, and is tightened through a subcutaneous access port by the injection or withdrawal of fluid (Figure 34.2). In VSG the stomach is transected vertically thereby creating a gastric tube and leaving 100–200 mL-size pouch (Figure 34.3). VSG has been shown to have metabolic effects comparable to RYGB [11]. VBG is a procedure that is not commonly performed currently, but which was used in landmark studies such as the Swedish Obese Subjects (SOS) study. In this procedure, the superior stomach is stapled vertically to create a pouch which is then separated from the rest of the stomach with a band.

BPD comprises a partial gastrectomy with formation of a 400 mL gastric pouch [12]. The small bowel is divided 250 cm proximal to the ileocecal valve, and the alimentary limb is connected to the gastric pouch to create a Roux-en-Y gastroenterostomy. An anastomosis is performed between the excluded biliopancreatic limb and the alimentary limb 50 cm proximal to the ileocecal valve. In BPD-DS, a VSG is constructed and the division of the duodenum is performed immediately beyond the

pylorus. The alimentary limb is connected to the duodenum, whereas the biliopancreatic limb is anastomosed to the ileum 75 cm proximal to the ileocecal valve (Figure 34.4) [13].

There are several endoscopic techniques in development that aim to replicate some of the metabolic effects of surgery [13]. Endoscopically placed synthetic duodeno-jejunal bypass liners such as the EndoBarrier© have been developed as an alternative to bariatric surgery and can result in a mean weight loss of 10–15% [14]. Complications such as sleeve migration and bowel obstruction can occur with the current technology, and the device produces gastrointestinal side-effects in many recipients. Given these limitations and the lack of long-term data, the role for devices such as EndoBarrier© remains to be determined.

Weight loss after bariatric surgery

The dominant effect of bariatric surgery, which is probably responsible for the majority of the metabolic benefits at least
Figure 34.2 Adjustable gastric band: the pressure applied through the band can be adjusted by injection or withdrawal of solution through the access port. (For a color version of this figure, please see the color plate section.)
Figure 34.3 Sleeve gastrectomy: this procedure does not alter the direction of nutrient flow through the gut. (For a color version of this figure, please see the color plate section.)

in the longer term, is sustained weight loss [9,10,15,16]. Depending on the type of surgery, maximal weight loss usually occurs 12 months postoperatively, with peak total weight loss of 33% after RYGB [17]. While RYGB results in greater weight loss than AGB in most studies, high-quality postoperative care after AGB can result in weight loss comparable to RYGB [18,19]. There are no differences in weight loss after RYGB and VSG 36 months postoperatively [20]. Longer term data on VSG are scant at present, but the data that are available suggest that significant weight regain may be frequent [21]. While BPD results in greater weight loss than RYGB, the complication rate is also higher [22,23]. Despite greater weight loss, metabolic and quality of life outcomes are comparable between RYGB and BPD in patients with BMIs above 55 kg m^{-2} [22,23].

In a minority, peak weight loss can be met by 6 months postoperatively, or may not be achieved until 24 months postoperatively (16). However, some weight regain is common thereafter and the mean 10-year weight reduction is 25% for RYGB and 13% for AGB [1]. Weight regain is described after all major procedures, but the etiology of regain is complex and multifactorial. Factors such as follow-up protocols can be as important as the

type of procedure, and many patient-specific factors can influence weight outcomes significantly after RYGB and AGB [24]. Longer term data on VSG are still awaited and this represents a reason for caution with this relatively new procedure [21].

Mechanisms of weight loss

RYGB was initially designed to combine malabsorption and restriction. However, using markers such as serum albumin and fecal fat, RYGB does not appear to result in malabsorption [25,26]. After RYGB, the reduction in combustible energy absorption is moderate (6–11%) [25]. Therefore, malabsorption is not usually a major mechanism of weight loss. Malabsorption may become more important in those with shorter lengths of the intestinal limbs, or in those who maintain high-fat diets after RYGB.

BPD has a greater malabsorptive effect than RYGB, and BPD recipients can consume over 3000 kcal daily and still maintain long-term weight loss [27]. Increased fecal fat, steatorrhea, and hypoalbuminemia after BPD are common [27]. This is consistent
Figure 34.4 Biliopancreatic diversion: the combination of sleeve gastrectomy and intestinal rearrangement results in significant changes to the metabolism, but can result in malabsorption. (For a color version of this figure, please see the color plate section.)

with malabsorption, suggesting that this is a significant contributor to weight loss after BPD. Fecal caloric density is not altered by VSG in animals but there are no data in humans [28]. VSG and AGB are not considered to produce significant macronutrient malabsorption.

AGB reduces stomach volume, and food within the smaller stomach pouch results in early gastric distension [29]. However, there is a lack of compensatory, high calorie seeking behavior in the majority of patients after AGB, which might be expected in the context of reduced food volume. The rapid weight gain seen after reversal of AGB suggests a physiologic attenuation of appetite that is modulated by the band [30]. Indeed, changes in appetite are reported following AGB [31–33]. Gut hormones that induce satiety, such as glucagon-like-peptide 1 (GLP-1) and peptide YY (PYY), are not altered by AGB, and inhibition of gut hormone responses with octreotide (a somatostatin analogue) does not affect food intake in AGB recipients [32,33]. Therefore, it is likely that AGB exerts its effects on satiety by neural signalling, probably through the vagal nerve and its branches [30]. This is supported by data that show increased satiety associated with increased pouch pressure [34]. Pouch emptying rates and

changes in pouch pressure are not associated with satiety, but the dilatation or pressure effect on the gastric pouch produces a satiation effect in the absence of any consistent change in gut hormones [33].

The mechanisms to explain weight loss after VSG are not fully elucidated. Gastric emptying and intestinal transit appear to be faster after VSG unless the antrum is preserved [35–39]. The generation of high intraluminal gastric remnant pressures and the disruption of the gastric pacemaker at surgery may explain these effects, and why anorexigenic gut hormones such as GLP-1 and PYY are elevated after VSG in magnitudes similar to RYGB. More studies examining the mechanisms behind VSG are required.

RYGB reduces stomach volume, which may produce early gastric distension and early satiety resulting in reduced meal size [29]. We would expect that reduced meal size volume results in a compensatory increase in appetite for calorie-dense food. However, RYGB patients report reduced hunger, increased satiety, and lower consumption of energy-dense foods postoperatively [30]. Therefore, it is not simply a matter of gastric pouch size. Randomized controlled trials have shown that the similarly "gastro-restrictive" procedure of VBG, results in less weight loss and less change in food preferences as compared to RYGB [40]. Hormonal and neural signals likely play important roles in this effect.

Satiety: the role of gut hormones and neural signals

Increased satiety and decreased hunger occur within days following RYGB, and this is associated with changes in the postprandial levels of gastrointestinal hormones that induce satiety, such as GLP-1 and PYY [31–33]. Postprandial levels of PYY and GLP-1 are increased from the second postoperative day after RYGB, prior to significant weight loss. Stimulated PYY and GLP-1 levels correlate with the amount of weight loss [31–33]. Inhibition of PYY and GLP-1 responses with a somatostatin analogue (octreotide) in patients after RYGB increases food intake, suggesting an important role of gut hormones in mediating enhanced satiety after RYGB [32].

Vagal nerve afferents are activated by the presence of nutrients in the upper gastrointestinal tract, and the perioperative preservation of vagal fibers results in greater sustained body weight loss after RYGB [41]. Thus, the rapid entry of food from the esophagus, through the small gastric pouch and the larger gastrojejunostomy, may trigger neural signals in the alimentary limb, which may contribute to long-term weight maintenance after RYGB [42,43].

These neural signals interact with gut hormone signals centrally to affect eating behavior, in association with other cues from the available food resources. These can be termed internal signals (such as gut hormones and vagal-mediated neural signals) and external signals (food cues, palatability, availability). The orbitofrontal cortex, hypothalamus, brainstem, and corticolimbic areas process sensory information and then

coordinate energy homeostasis by modulating food searching, sensing, and reward. Higher cortical centers implicated in emotional responses can influence food intake to provide reward, and this intake can exceed the requirements of energy homeostasis [44]. Dysfunction of this reward network may contribute towards dysfunctional eating and the development or maintenance of obesity [45].

Postoperatively, RYGB recipients tend to reduce meal size but increase meal frequency [46]. In randomized controlled studies, VBG results in a higher proportion of fat and carbohydrates in the diet compared to RYGB recipients, who prefer fruit and vegetables and have a reduced preference for high-fat foods [40]. Compared to VBG, RYGB patients tend to avoid calorie-dense foods, and prefer high glycemic index foods [47]. In addition, the reward areas of the brain are less active when presented with high calorie food after RYGB [48,49]. Therefore, RYGB remediates some "reward dysfunction," and hormonal or neural signals may be implicated. This control mechanism remains to be fully elucidated, but is likely to be important in the effects of RYGB on weight and metabolic health.

Energy expenditure

In rodents, energy expenditure increases after RYGB despite reduced calorie intake [50,51]. In humans, the data are scanty and inconsistent, partly as a result of the inherent difficulty in measuring energy balance in humans [52–58]. Chronic calorie restriction normally produces a decrease in resting energy expenditure [50] and diet-induced thermogenesis is impaired in insulin-resistant subjects [59]. Therefore, increased insulin sensitivity is expected to enhance diet-induced thermogenesis [54]. Energy expenditure reflects the mass of metabolically active tissue, resting energy expenditure generally must be reduced postoperatively due to the loss of lean body mass along with the loss of fat mass. Whether such reduction is strictly proportional to the loss of lean tissue in all patients and with any surgical procedure is uncertain. The following diet-induced weight loss energy expenditure is less than predicted by the loss of lean mass and can contribute to weight regain [60]. Finally, in weight-reduced subjects who increase their physical activity, the associated increase in energy dissipation may be important, although moving a substantially leaner body costs less energy [55]. The postoperative changes in energy expenditure are likely to be the algebraic sum of all of these changes, and can therefore produce great variability within and between subjects.

Treatment of diabetes and related metabolic diseases

The current patient selection criteria for bariatric surgery focus on BMI, with a value of 40 kg m^{-2} as the threshold for surgery in those without recognized comorbidities. Comorbidities, including metabolic disorders such as diabetes, lower the BMI

threshold for surgery to 35 kg m^{-2} [61,62]. Bariatric surgery for individuals with a BMI less than 35 kg m^{-2} with obesity-related comorbidities is currently an area of intense investigation, but is not generally recommended [63].

Data in patients with BMI less than 35 kg m^{-2} show that bariatric surgery can produce weight loss that brings them into the nonobese range, with associated improvements in fasting glucose levels and lipid profiles [64]. These data are mainly based on studies of RYGB and BPD [64]. In subjects with diabetes, over 80% achieve a HbA1c of less than 7% (53 mmol mol^{-1}) with a 3% major complication rate and no mortality [64]. This effect can be durable, with prospective data reporting 88% that RYGB recipients with a BMI of 30–35 kg m^{-2} maintain a HbA1c less than 6.5% (48 mmol mol^{-1}) 6 years postoperatively [65].

BPD improves glucose homeostasis even in those with BMIs less than 35 kg m^{-2}, a mean duration of T2DM of 11 years, and suboptimal glycemic control with a mean HbA1c of over 9% (75 mmol mol^{-1}) [66]. Over a 1-year follow-up period, over 80% of this cohort achieved HbA1c levels less than 7% (53 mmol mol^{-1}) and remained off antidiabetic therapy without excessive weight loss [66]. These data show that bariatric surgery could be considered in those with a BMI less than 35 kg m^{-2} in the presence of diabetes, especially in those who are not meeting their treatment targets despite intensive medical therapy. Based on a recent systematic review, bariatric surgery in such candidates would improve HbA1c from high-risk ranges to near-normal ranges [67].

This has led the IDF to recommend that bariatric surgery be considered for treating T2DM in patients who are not adequately responding to medical treatment with a BMI of 30 kg m^{-2} or greater [68]. This is a development of the metabolic surgery paradigm. In addition to the well-documented effects on glucose homeostasis, there are emerging data to suggest that bariatric surgery may have a role in the treatment of diabetic complications such as diabetic kidney disease [69,70].

Diabetes remission

Diabetes remission is widely discussed as an outcome of bariatric surgery, but remission following bariatric surgery is often transient [1,2]. Recurrence of T2DM is associated with longer durations of T2DM preoperatively, less weight loss postoperatively, and postoperative weight regain [71]. Recently, it has been recognized that remission may be an unhelpful goal, and that surgery should instead be recognized as another method for achieving long-term glycemic control in patients in whom less invasive therapies have failed. A major difficulty in interpreting these data are the differing definitions of remission, and differing time frames in study follow-ups. In the Swedish Obese Subjects study, approximately 50% of those who entered remission at 2 years after surgery had recurrence of diabetes at 10 years, although they were still left with much better glycemic control than presurgery [1]. After 6 years, RYGB reduced HbA1c to less than 6.5% (48 mmol mol^{-1}) in 62% of patients when used in conjunction with best medical therapies [72].

This differs from the current American Diabetes Association definition of diabetes remission as a HbA1c less than 6% (42 mmol mol^{-1}) and a fasting glucose less than 5.6 mmol L^{-1} off glycemic therapy [73]. This definition is controversial as many believe that it encourages clinicians to discontinue medication instead of using surgery as an add-on therapy to current medical therapy [73].

In the studies above, remission of diabetes was not a primary outcome when the participants were selected for bariatric surgery [16–18]. The candidates had a wide range of "metabolic phenotypes" [16–18]. Certain metabolic characteristics determine the likelihood of remission after surgery, and duration of diabetes and level of glycemic control preoperatively are important factors. Those with a greater duration of diabetes, higher preoperative HbA1c values, insulin dependence, and less weight loss are less likely to achieve postoperative remission of diabetes after RYGB or VSG [74]. Heterogeneous clinical characteristics of the cohorts with diabetes in the available studies, and ongoing changes in the definition of diabetes remission during the period of these studies, make interpretation of the data more difficult. Nevertheless, using the current American Diabetic Association criteria (a HbA1c less than 6% (42 mmol mol^{-1}) and a fasting glucose less than 5.6 mmol L^{-1} off glycemic therapy, diabetes remission occurs in at least 34% of all recipients of RYGB, VSG, and AGB at a mean follow-up of just under 2 years [73]. RYGB has greater efficacy in this regard, with a remission rate of over 40%, as compared to 26% of VSG and 7% of AGB, but selection bias may heavily influence these data, as may greater weight loss when compared to AGB [73]. Future studies on glycemic control should apply the same definitions to allow comparison between results.

The evidence to date supports that surgery should be considered as an add-on therapy for diabetes, where it can be expected to induce transient remission in those with shorter duration of diabetes and better glycemic control preoperatively. Remission as a goal of treatment would preselect candidates on the basis of the duration of their diabetes, and on the range of their hyperglycemia, rather than focusing on patients where less invasive therapies have failed and where surgery could add the most benefit when used with best medical care. The patients with a longer history of diabetes and uncontrolled hyperglycemia are less likely to remit, but may also be more likely to benefit as they are at a much higher risk of developing micro- and macrovascular complications. This would suggest that diabetes remission should not be the objective. Instead, it could be argued that the clinical objective should be to improve glycemic control in those with advanced metabolic disturbance, as evidenced by uncontrolled hyperglycemia, or those either at high risk of diabetic complications or with diagnosed diabetic vascular disease.

Improving glycemic control with bariatric surgery

Bariatric surgery with medical therapy produces greater glycemic control compared to best medical therapy alone, or surgery without best medical therapy [6,7,75]. In randomized controlled trials, RYGB, BPD, VSG, and AGB are superior for improving glycemic control than medical therapy alone [6,7,76]. In adults with BMIs of 30–40 kg m^{-2} and a duration of T2DM of less than 2 years, AGB can result in over 70% or patients with T2DM achieving a HbA1c of 6.2% (44 mmol mol^{-1}) or less, as compared to less than 15% of those on medical therapy attending a diabetes multidisciplinary team for review every 6 weeks [76]. Note that the improved glycemic control was in the context of a 10-fold greater weight loss in the AGB group as compared to the medical group over a 2-year follow-up period [76].

In another randomized controlled trial comparing BPD, RYGB, and medical therapy in patients with a BMI of 35 kg m^{-2} or more and T2DM for at least 5 years, 95% of BPD recipients achieved HbA1c ≤ 6.5% (48 mmol mol^{-1}) compared to 75% of RYGB recipients and 0% of the medical treatment group over 2 years [7]. Participants in the intensive medical arm attended a diabetes multidisciplinary team every 12 weeks for optimization of their diet, lifestyle, and medical therapy [7]. Over the 2-year study period the intensive medical therapy group lost nearly 5% of their baseline weight, compared to over 30% weight loss in both surgical groups [7]. In other randomized controlled data testing RYGB and VSG against intensive medical therapy administered along American Diabetes Association guidelines, a HbA1c of 6% (42 mmol mol^{-1}) was achieved by 42% of the RYGB group combined with best medical care, 37% of the VSG group combined with best medical care, and 12% of the medical group [6]. The cohort were obese, had T2DM for a mean duration of over 8 years, and were not meeting their current glycemic targets [6].

These studies were the first to use bariatric surgery as "add-on therapy" to best medical care. Metformin, lipid pharmacotherapy, and renin-aldosterone-angiotensin system antagonists were continued after surgery where possible. The study cohorts represent those with significant metabolic disturbance refractory to medical therapy, who are the patient cohort that struggles to achieve safe treatment targets with nonsurgical treatments. These data demonstrate that in a selected group, surgery combined with best medical care can be the optimal therapeutic approach.

However, long-term data is needed before making final judgment. Glucose homeostasis worsens in the first 2 postoperative years after bariatric surgery [1,68]. Therefore, longer follow-up of these cohorts is necessary to ensure that the effects are durable. Further studies on cost–benefit and risk–benefit ratios should be performed to ensure that the complications and cost inherent in bariatric surgery do not outweigh the benefits in this group.

Bariatric surgery and microvascular complications

The improved glycemic control associated with bariatric surgery could be expected to reduce the burden of vascular complications in diabetic cohorts. So far there have been no randomized controlled trials examining the effect of bariatric

surgery on microvascular outcomes; however, observational data support the hypothesis that bariatric surgery may have a role in managing not only diabetes, but also its complications.

Most of the available data on microvascular diabetic complications are on diabetic kidney disease. In a retrospective analysis of 25 RYGB patients, renal function improved from an impaired baseline estimated glomerular filtration rate (eGFR) of 48 mL min^{-1} 1.73 m^{-2} to over 60 mL min^{-1} 1.73 m^{-2} [77]. The difficulty with these type of data is that they may be falsely reassuring as any weight loss will reduce serum creatinine; thus, the improved eGFR estimation based on the Modified Diet in Renal Disease (MDRD) formula may reflect the reduction in lean body mass rather than improvements in renal function. Some studies have used other measurement techniques of GFR such as creatinine clearance and urinary cystatin C:creatinine ratio, and found that RYGB improves renal function in cohorts with or without diabetes [78]. There are few studies in which the effect of the surgical procedure itself on renal function can be assessed independently of weight loss. This is an area that needs further specific investigation.

Markers of kidney damage such as the albumin:creatinine ratio indicate early diabetic kidney disease. Improvement in proteinuria can be demonstrated up to 2 years postoperatively following bariatric surgery in patients with T2DM [79]. Bariatric surgery can improve albumin:creatinine ratios over a 5-year period [80]. Case–control data at 10 years comparing BPD and medical therapy show a steady decline in renal function in the medical group, with stabilization of eGFR and remission of albuminuria in the BPD group [81].

For retinopathy and neuropathy, there are fewer data on outcomes following bariatric surgery. Results from a cohort study 1 year after RYGB, VSG, and AGB report no change in retinopathy scores in a group with T2DM [70]. This is reassuring, given the dramatic improvements sometimes seen in glycemic control after bariatric surgery, which could be expected to worsen retinopathy [6,7,76].

Bariatric surgery does not have a proven role in treating those with microvascular complications, but early evidence suggests that it may be useful, at least in diabetic kidney disease [77,78,80,82]. There are no data to support the use of bariatric surgery in treating diabetic retinopathy or neuropathy, but the available data suggest that it is not deleterious in retinopathy. Given that there are no micronutrient or vitamin deficiencies, then it would not be expected to worsen neuropathy.

Bariatric surgery and other comorbidities

As well as the effects on diabetes, bariatric surgery has beneficial effects on dyslipidemia and hypertension [1,83,84]. Ten years postoperatively, bariatric surgery patients had lower rates of hypertension and hypertriglyceridemia, and increased high-density lipoprotein (HDL) concentrations, when compared to a matched control group [1]. This may contribute to the lower cardiovascular mortality associated with bariatric surgery over 15 years [2]. Those with BMI less than 35 kg m^{-2} also benefit in terms of cardiovascular risk reduction [85,86]. In this group, bariatric surgery, including RYGB, improves blood pressure and lipid profiles in tandem with improvements in glucose homeostasis [85,86].

However, the data are controversial. It may be that the persistent use of lipid or antihypertensive pharmacotherapy is responsible for the reduced blood pressure and improved lipid profiles in some cohorts [63]. In meta-analyses of the data on bariatric surgery within cohorts with BMI less than 35 kg m^{-2}, there is a reduction in total cholesterol and triglyceride concentrations, but HDL levels are unaffected [64]. Many studies do not adequately report associated pharmacotherapy and therefore these data should be interpreted with caution. Although the use of bariatric surgery to treat cardiovascular risk in those with BMI greater than 35 kg m^{-2} is not formally proven, it seems reasonable given the long-term data of almost 20 years' duration that demonstrates this [2]. Further longitudinal studies in this area are needed with emphasis on the lower range BMIs and cardiovascular and metabolic outcomes. The available evidence is less convincing in those with BMI less than 30 kg m^{-2}. While a strong argument cannot be made for treating cardiovascular risk with bariatric surgery in the lowest BMI ranges at present, it should continue to be evaluated and may be worth considering in those with extremely high cardiovascular risk that is refractory to medical therapy.

Mechanisms of diabetes remission and improvement in glucose homeostasis

There are several postulated mechanisms responsible for the improvement in glucose homeostasis after bariatric surgery. It is widely recognized that weight loss has major positive implications for metabolic health, and therefore it has been thought that the metabolic benefits derived from bariatric surgery are simply due to weight loss alone. However, there are multiple other mechanisms that can additively improve metabolic outcomes after bariatric surgery. They include hormonal changes, effects on appetite, and changes in insulin sensitivity. In fact, these all probably act in concert, but each mechanism will be discussed individually.

Insulin resistance

Insulin resistance is associated with obesity, and thus is a key factor in the development of most cases of T2DM [10–15]. Hepatic insulin resistance manifests as a rate of glucose production that is inappropriately elevated for the prevailing plasma glucose and insulin levels. Peripheral insulin resistance manifests as impaired insulin-mediated glucose disposal by target tissues (mostly, skeletal muscle and adipose tissue). The latter is directly measured by the euglycemic hyperinsulinemic clamp technique, while the former requires the use of glucose tracers (HOMA-IR being a crude surrogate). Hepatic insulin resistance

is present in obese subjects with or without T2DM. Calorie restriction lowers plasma glucose and insulin concentrations and hepatic glucose production, whereby hepatic insulin resistance is improved. As early as a few days after surgery, before any weight loss, hepatic insulin sensitivity ameliorates likely due to the severe caloric deficit, with reductions in resting metabolic rates [87–89]. These improvements continue for up to 12 months postoperatively, and have been shown in both animal and human studies [90–92].

With regards to mechanisms, the "foregut hypothesis" posits that bypass of the proximal small bowel reduces the secretion of unknown gastrointestinal factors that decrease insulin secretion and promote insulin resistance. Accordingly, duodenal exclusion would reduce production of these putative "anti-incretins" leading to an increase in insulin secretion and action [93]. However, clamp studies have consistently shown that peripheral insulin resistance does not improve after RYGB as promptly as hepatic insulin resistance [87,91,94,95]. In the longer term (up to 6 months), insulin-mediated glucose uptake is enhanced by RYGB in both diabetic and nondiabetic recipients, and quantitatively the improvement is roughly proportional to the amount of weight loss [95]. Furthermore, in studies comparing RYGB and AGB with equivalent weight loss, clamp-based insulin sensitivity was found to be similarly increased, confirming that in humans the bypass itself does not exert a weight-independent effect on insulin action [96]. In contrast, both BPD and ileal transposition have been shown to produce a rapid and partially weight-independent enhancement of insulin action in subjects both with and without T2DM [97–99]. This has led to a "hindgut hypothesis" whereby anticipated nutrient delivery to the distal gut triggers responses (hormonal signals, substrates, neural reflexes) that potentiate insulin action [100,101].

In summary, bariatric surgery impacts on insulin action through different mechanisms and in different time courses. In the early postoperative period, calorie restriction improves hepatic insulin resistance, and later, weight loss restores peripheral insulin sensitivity. Throughout the postoperative period, the fall in glycemia relieves glucose toxicity. Altering the sequence of nutrient contact with the distal gut mucosa likely engages additional mechanisms of insulin sensitization. This does not fully account for the effects of bariatric surgery on glucose homeostasis, and enhanced hormonal activities postoperatively, including insulin secretion, are major contributors.

Insulin secretion and β-cell function

β-Cell function is an important component of the effect of bariatric surgery on glucose metabolism, expecially in the diabetic patient, and impacts β-cell function by improving secretory dynamics in the face of reduced absolute insulin secretion rates. In fact, both the acute insulin response to intravenous glucose (AIR) and glucose sensitivity in response to oral glucose or mixed meals are improved early after surgery, and continue to improve as insulin resistance abates. Very low-calorie diets are associated with improvements in first-phase insulin secretion

in obese cohorts with diabetes as compared to BMI-matched control groups [102]. While this may be a contributing factor, incretin hormones have been implicated in the improvements in insulin secretion after surgery, and GLP-1 is consistently associated with improved insulin secretion [103,104]. Bariatric procedures vary in how they enhance the incretin response, and RYGB has a greater effect on these hormones than AGB [5,105]. RYGB results in increased insulin secretion after eating when compared to patients with equivalent calorie restriction over 2 weeks in nondiabetic matched groups with matched weight loss [95]. An enhanced postprandial GLP-1 response is associated with this improved insulin secretion [88,90,94,95].

Here, the foregut and hindgut hypotheses may converge in that an accelerated delivery of nutrients to the distal gut improves β-cell function through an enhanced secretion of gut hormones such as GLP-1 and PYY. Thus, both VSG and RYGB potentiate β-cell function from the early postoperative period [106]. Support for this general mechanism comes from studies examining the effects of flexible plastic sleeves that prevent nutrient contact in the duodenum. These devices result in improvement in glucose homeostasis shortly after insertion [107]. Further support comes from experiments involving ileal interposition [104,108]. In this operation, a segment of the ileum rich in GLP-1 and PYY secreting cells is transplanted into the upper intestine, near the duodenum-jejunum boundary, thereby increasing exposure to ingested nutrients [108].

It must be emphasized that in T2DM, bariatric surgery may improve β-cell function but may fail to restore it to the level of nondiabetic individuals. Correspondingly, diabetes remission may be incomplete or transient. Available evidence indicates that the strongest predictor of failure to induce remission of diabetes is low β-cell function preoperatively, such as is seen in patients with long-standing severe hyperglycemia [109].

Appetite and energy expenditure

There is no doubt that reduced food intake modulates improvements in glucose homeostasis after bariatric surgery. Bariatric surgery is associated with improved satiety and reduced appetite through central and humoral mechanisms [32,75,110]. This effect is regulated through a complex neuroendocrine network that is still being defined [110,111]. RYGB can increase the secretion of satiety promoting gut hormones including PYY and GLP-1 [112,113]. The neural pathways regulating energy intake and energy expenditure includes the arcuate nucleus, which has PYY receptors [111,114]. Pharmacologic antagonism of PYY and GLP-1 results in increased appetite in recipients of RYGB and AGB [112]. Therefore, the enhanced gut hormone response has a central effect on appetite after surgery [32,114].

However, there are also effects on enteroneural systems involving the vagus nerve and its network. The contribution of GLP-1-mediated vagal responses in regulating appetite is not fully understood [115,116]. Selective vagotomy can impair glycemic control, and have some effect on appetite, but vagotomized rats eat less than controls [116]. Studies comparing

central and intraperitoneal administration of GLP-1 in vago-tomized rats suggest that there is significant contribution to satiety from both central and vagal incretin stimulation [111]. Further studies are needed to establish how the enteroendocrine system interacts with the central nervous system to affect satiety.

Changes in the pattern of substrate oxidation may affect the appetite/satiety balance. During surgically induced weight loss, there is preferential oxidation of fat over carbohydrate due to lower plasma insulin concentrations and enhanced lipolysis [87,117]. Raised circulating ketone bodies characterize the phase of rapid weight loss postoperatively [118]. GLP-1 and the GLP-1 receptor agonist, oxyntomodulin have also been implicated in the postoperative decrement in calorie intake, whether by direct central relays or through the slowing of gastric emptying [119–122].

Mechanisms of diabetes remission: other perspectives

Alterations in the total or individual species levels of bile acids in the gut and circulation have been implicated in improvements in glucose metabolism induced by bariatric surgery. Bile acid levels in the plasma are increased after RYGB, which has a significant early effect on improving glucose homeostasis, whereas AGB does not change plasma bile acid levels [123–126]. The level of bile acid fractions in plasma negatively correlates with glycemic excursions, implicating bile acids as agents in glucose homeostasis [123].

Bile acids can directly or indirectly affect glycemic control through several pathways, including the TGR5 receptors or nuclear FXR receptors, and the release of fibroblast growth factors (e.g. fibroblast growth factors 19 and 21), which exert actions on a wide range of tissues including the hypothalamus [127–129]. A central effect on food intake and appetite is possible, as bile acids can cross the blood–brain barrier and act on receptors in the hypothalamus [127–131].

The effect of bile acids may be to augment postprandial secretion of GLP-1 and other gut hormones [124]. Increased bile acid secretion after RYGB is associated with greater gut hormone levels [41]. Plasma bile acids are also elevated in animal models of VSG [132]. Bile acids could affect food intake, energy expenditure, and glycemic control through their actions on membrane TGR5 receptors or nuclear FXR receptors and the release of fibroblast growth factors. However, in the absence of detailed mechanistic studies, the exact role of bile acid as mediators of weight loss and glycemic control after RYGB remains unclear. Preclinical and clinical studies are underway to determine their physiologic effects, and their therapeutic potential.

Gut microbiota in the context of obesity and weight loss have also been identified as important metabolic mediators after bariatric surgery, and bacteria have been implicated in the development of obesity [133]. Bariatric surgery can alter the gut microbiota, and a depletion of *Prevotellaceae*, *Archea*, *Firmicutes*, *Bacteroidetes* colonies, and an increase in the *Bacteroidetes/Prevotella* ratio and *Gammaproteobacteria* of this flora

has been observed after RYGB [134–136]. These alterations can be associated with weight loss. The etiology of these changes is unclear, but may involve alterations in dietary macronutrient composition, anatomical manipulations, pH, and bile flow.

While the microbiota may change as a result of surgery, they have been shown to affect the surgical recipient. Adoptive transfer of gut bacteria from RYGB recipient mice to unoperated germ-free mice results in weight loss and increased energy expenditure [137]. This novel finding suggests that probiotic therapy could modulate energy homeostasis and potentially glycemic control. However, the exact mechanisms through which gut bacteria contribute to weight loss remain to be determined, and similar studies remain to be completed in humans.

Conclusion

Bariatric surgery is an effective treatment when combined with best medical care for obesity and obesity-related comorbidities including diabetes. However, many questions remain unanswered, including the role of bariatric surgery in treating metabolic diseases beyond diabetes, and the effect on diabetic complications.

The mechanisms of the effects of bariatric surgery are multiple, and include changes in body weight, appetite, food intake, gut hormone secretion, and resultant improvements in insulin resistance and insulin secretion. The effects on energy expenditure may also be important. Other mechanisms such as bile acids and microbiota are likely to also play a role, but more data on these pathways are needed.

Animal models of obesity and type 2 diabetes

David A. York, Mie Jung Park-York and Timothy Gilbertson
Department of Biology, Utah State University, Logan, UT, USA

Key points

- Application of new genetic technologies has facilitated the development of many new models.
- Genetic technologies have enabled proof of function experiments for specific genes or specific signaling pathways.
- The functional role of a specific protein in a specific cell type can now be studied by targeted gene knockouts or expression.
- Simple organisms (*C. Elegans* or *Drosophila*) also provide useful models for studying specific gene functions.
- Epigenetic changes associated with the early *in utero* and neonatal environment may have major effects on the development of obesity and its associated comorbidities.
- Recent identification of the role of the gut microbiome in promoting health has led to the development of numerous animal models that have enabled greater insight into potential mechanisms.
- Animals provide good models for understanding the mechanisms through which bariatric surgery has its beneficial effects in reducing obesity and type 2 diabetes.
- Application of animal modeling approaches will help to identify the physiologic roles of fatty acid binding proteins.

Introduction

Animal models have made a huge contribution to our understanding of obesity and type 2 diabetes (T2DM), providing insight into the causes and the pathophysiology of the conditions and their molecular and genomic underpinnings as well as providing evidence for new potential therapeutic targets [1,2]. From all of these studies has come the recognition that obesity and T2DM results from an interaction between the organism's genetic susceptibility and the environment in which it lives. This is true of both vertebrate and nonvertebrate animals. Thus it is not surprising that there is now a voluminous literature on environmental and genetic influences that can modulate the susceptibility to becoming obese and diabetic. However, with the development of new and selective targeting techniques, the focus has changed from identifying genes that cause, predispose, or facilitate the development of obesity and T2DM to one in which selective gene targeting is used to develop insight into the roles of specific signaling pathways and for proof of function of specific genes. It is not the intention of this chapter to provide a comprehensive review of all these animal models. Indeed this would take a book by itself. Readers are referred back to a previous review for information on earlier models [1]. Instead, the focus will be on identifying the differing approaches that have been and are being utilized in animal studies more recently to further our insight into these metabolic conditions, while providing some specific examples of the insight that has been gained. In addition, we shall focus on two emerging areas where the use of these technological approaches is likely to lead to real advances in our understanding in forthcoming years.

Early models of diabetes and obesity were mainly in spontaneous mutations identified in laboratory rodents that were subsequently identified as being related to leptin signaling or melanocortin signaling or in studies across rodent strains that significantly differed in their response to high-fat diets (HFD) [3,4]. While the ability to manipulate gene expression in the whole animal has effectively maintained the focus on mice and rats, there has also been an explosion of interest in other species from the nematode worm *Caenorhabditis elegans* (*C. elegans*) and the *Drosophila* fruit fly up to primates. The latter have provided substantial insight into the temporal changes associated with the development of T2DM in obesity [5]. Since nutrient sensing is a requirement for all levels of organism, studies in simple organisms has helped to identify genes that may function in metabolic control in higher organisms. Thus flies with an insertion at the *Atf4* locus lack fat and have increased susceptibility to starvation. Subsequent knockout of the *Atf4* gene in mice identified a similar function; the mice were lean and were resistant to diet-induced obesity, diabetes, and hyperlipidemia [6]. The nematode *C. elegans* provides an inexpensive model that has attracted increasing attention for

a wide range of studies as it includes many of the same genes or gene homologs that are found in higher animals. Its short lifespan, rapid accumulation of fat and known genome sequence have provided an excellent model for studies including genetics, feeding and satiety, metabolism, as well as the screening of potential therapeutics. For example, study of the tub-1 mutation in *C. elegans* has provided insight into the pathways through which this gene regulates fat storage and lifespan [7].

Environmental influences

Dietary composition, particularly the level and type of dietary fat and carbohydrate is the most common environmental change that is associated with the development of obesity in a wide range of animal species and humans [8]. Significant strain differences in the susceptibility to become obese and/or diabetic on a HFD have been identified in mice and rats [9], a clear indication of the multigenic genetic variability in susceptibility. Indeed, the response to introduction of a HFD has become the classic experimental condition that is applied to phenotype all genetically manipulated animals for their susceptibility to become obese. Numerous gene linkage studies have been applied to these strain differences with only limited success in identifying genes of causality. However, selective breeding of animals prone to or resistant to obesity has enabled the identification of numerous physiologic differences associated with these different susceptibilities. An example of these are the studies of Levin and colleagues [10,11] which have identified differences in CNS signaling that could be linked to the differing susceptibility to become obese. These include differences in axonal pathways between the arcuate and PVN in the hypothalamus that are associated with both leptin and insulin regulation of feeding behavior through actions on the NPY/AgRP and POMC neurons [11]. Notwithstanding this, manipulation of the fatty acid composition of HFD has identified the differential effects of saturated as opposed to N-3 polyunsaturated fats in promoting or protecting, respectively, against the development of diabetes. Other dietary manipulations that have provided insight into the development of obesity include high sucrose, cafeteria diets, and diets with excessive zinc content. Alternatively, even the provision of standard laboratory chow can induce obesity and diabetes in susceptible rodent strains, for example the sand rat whose normal desert habitat has a scarcity of food supply.

Early environment and epigenetics
In recent years there has been the exciting recognition that the environmental influences on the development of obesity and diabetes are far greater than diet alone. From the early studies of Barker and colleagues [12] on the effects of maternal malnutrition on the health of the adult offspring, many animal models for the epigenetic regulation of obesity and T2DM have evolved. Studies in rodent species as well as larger animals

have shown the association between maternal obesity and a sarcopenic form of adult obesity in the offspring who develop a metabolic syndrome phenotype associated with increased fat and reduced muscle mass, insulin resistance, and hypertension [13,14]. Further studies of this model suggest that the chronic inflammation that is associated with maternal obesity may expose the fetus to increased placental proinflammatory cytokines and reactive oxygen species [15]. These changes may persist across generations through both maternal and paternal lineages.

Obese mothers also potentially expose their offspring to higher levels of insulin and leptin during both fetal development *in utero* and during the early suckling period. Insulin injections into the dam or direct injections into the hypothalamus during the first 8 days of life are both associated with the development of future obesity in the adult. It is also clear that leptin injections into neonatal *ob/ob* mice can repair the defects in axonal pathways between the arcuate and PVN. Hence, it is not clear if the phenotypic results of these early life manipulations represent epigenetic changes or changes in the development of neuroanatomical pathways and functions.

The studies of epigenetic effects has not been limited to rodent models but has also been investigated in farm animals such as sheep and pigs. These epigenetic changes in gene expression have been associated with modification of histones by acetylation and methylation and with methylation of the promoter regions of genes. For example, moderate maternal undernutrition of sheep was associated with changes in histone methylation and acetylation of the glucocorticoid receptor (GR) gene whereas promoter methylation led to changes in POMC gene expression in the offspring [16]. Similarly maternal HFD may significantly change the expression of genes in multiple brain regions that lead to alterations in behavior and energy balance [17].

Viral infections
Viral infections have long been associated with the development of obesity through their potential effects on hypothalamic regulatory systems [1] but more recently the focus has been on adipogenic viruses such as Adenovirus Ad36. This has been linked to mild obesity in a wide range of animal strains including humans. Ad36 is thought to upregulate adipocyte differentiation and proliferation as well as enhance triglyceride synthesis and deposition [18] but, at the same time, it improves glucose homeostasis. This is thought to be the combined result of Ad36 inhibition of IRS-1 tyrosine phosphorylation that reduces insulin-stimulated glucose transport in the presence of Ad36 activation of RAS signaling that independently enhances PI3K signaling and glucose transport [19].

The gut microbiome
Another major environmental influence on the development of obesity and T2DM is the gut microbiome [20]. Immediately after birth, the gut becomes rapidly populated with microorganisms that develop a symbiotic relationship with the host.

Germ-free mice are much leaner than conventionally raised mice [21,22] possibly due to the release of a lipoprotein lipase inhibitor and activation of hepatic and muscle AMPkinase that favors fatty acid oxidation. This may in turn reflect the absence of short chain fatty acids or immune activators such as bacterial lipopolysaccharide (LPS) normally produced by the microbiota in germ-free mice. High-fat diets lead to an increase in gram negative bacteria that produce LPS and this in turn activates proinflammatory cytokine production that will promote obesity and T2DM. Thus comparison of germ-free and conventional mice becomes an important model for demonstrating the role of gut microbiota on host metabolism and behavior [23]. Diet-induced obesity has been linked to major changes in the gut microbiome that are reversible by weight loss [24] and similar changes have been identified in humans. Prebiotic and antibiotic therapies also provide models for studying the role of the micobiota as do mice with mutations in the *MYD88* gene that is associated with the toll-like receptor response. Studies in these models indicated a role for the cannabinoid 1 receptor in modulating gut permeability [25]. Likewise, mice that lack toll-like 5 receptor in the gut mucosa are less able to defend against bacterial infection and develop a metabolic syndrome type phenotype that includes increased body weight and body fat, insulin resistance, hyperlipidemia, and hypertension [26]. Transfer of the gut microbiota from such mice into germ-free wild-type mice induced many of the metabolic syndrome characteristics suggesting the importance of the gut microbiota to the induction of metabolic disease [26]. Future studies of the role of the human gut microbiome may be aided by the transfer of the human microbiome into pigs [27].

Animal models, other than those that arise spontaneously, have generally been developed to explore the functions of specific genes or signaling pathways or to develop models for human disease. One exception to this is the microbiome models described earlier. Another example arises from the success of *bariatric surgical approaches* to reverse gross obesity and its comorbidities in human populations [28,29]. The mechanisms through which these various surgical approaches lead to a rapid improvement in comorbidities, such as T2DM, that appear to be independent of the weight loss, are not really understood. Changes in gastrointestinal anatomy have long been known to have significant impacts on energy balance [30]. Since gastrointestinal–brain communication is particularly difficult to investigate in humans, this has promoted the development of a number of animal models in which the gastrointestinal architecture has been altered to mimic those surgical procedures used in humans. These models have focused on sleeve gastrectomy, Roux-en-Y gastric bypass, and ileal transposition [31–33]. They allow detailed investigations of the temporal changes in gut and brain physiology that may identify the mechanisms that underlie the beneficial effects of these surgical procedures and when performed in genetically manipulated animals [33] can identify the potential role of specific signaling systems to the surgical response.

Genetic models

The initial studies of the genetic basis for obesity and T2DM relied upon spontaneously arising mutations in mouse and rat models. Study of such models led to the identification of the leptin gene (*ob/ob* mouse), the leptin receptor (*db/db* mouse and *fa/fa* and Koletsky rats), agouti and the melanocortin signaling system (A^y/a mouse) and did much to identify the signaling pathways in the CNS through which leptin and insulin can act to modulate energy balance. These have been extensively reviewed [1,34,35]. However, the subsequent development and use of a wide range of gene targeting techniques has led to a plethora of animal models. Thus, we have moved from these natural mutations through whole animal transgenic expression or gene knockout to techniques that allow tissue-targeted knockouts and overexpression and now, on to gene manipulation in specific target cells (Table 35.1). Such models have not only allowed the "proof of function" type of experiment but also allow detailed insight into the signaling pathways within the CNS and peripheral tissues that promote obesity and diabetes. In addition, they have enabled definition of the neuronal phenotypes and anatomical pathways through which energy balance and peripheral metabolism are regulated. Some examples of these approaches are provided in the following sections.

The identification of leptin and its signaling receptor from studies of natural mutation mice and rat models provided a major step forward in our understanding of the systems that underlie the regulation of energy balance. It identified leptin as a cytokine produced in adipose tissue that acted as a feedback signal to regulate food intake and energy balance [36]. This focused studies onto the hypothalamus where leptin receptors are expressed in both AgRP/NPY and POMC/CART neurons within the arcuate nucleus, neurons known to exert major stimulatory and inhibitory functions on food intake while also having anabolic and catabolic effects respectively on peripheral metabolism. Many of these effects were identified through animal models in which specific genes (*AgRP*, *NPY*, *POMC*, *MC4R*, and *MC3R*) were knocked out. This led to the general hypothesis that leptin inhibited the AgRP/NPY neurons and activated POMC/CART neurons to suppress feeding, activate sympathetic drive to the periphery and enhance catabolic pathways. However, the ability to *target gene knockouts to specific cell types using Cre-Lox technology* has enabled significant new insight. This has been accomplished in several ways, either by breeding the Cre and Lox animals together to knockout a specific gene universally or in specific cell types or in specific cell types within a local area by, for example, stereotaxic injections of adeno- or lenti-viral vectors containing the Cre recombinase (Figure 35.1). These approaches have provided new and unexpected insight into these regulatory pathways. For example, rescue of leptin receptors in the arcuate nucleus of *db/db* mice only partially reversed their hyperphagia [37] while the use of Cre/Lox technology to specifically delete leptin receptors in POMC neurons [38–40] only produced mild

Table 35.1 Progression of genetic approaches used in animal models

Approach	Example	Phenotype
1. Spontaneous models of genetic obesity	Single gene mutations(*Lep, Lepr, Agouti*)	Obesity ± Diabetes
2. Whole animal transgenics (Tg)/knockouts (KO)	Tg AgRP with β-Actin promoter MC3R KO	Obesity and coat color change Obesity without hyperphagia
3. Tissue targeted Tg or KO	Hepatic insulin receptor (*Insr*) KO *Hsd11b1* Tg on aP2 promoter	Diabetes Central adiposity
4. Gene manipulation in specific cell type	*Lepr* KO in POMC neurons	Mild obesity
5. Gene rescue in KO mice	*MC4R* rescue in PVN of *MC4R* KO mice	Prevented 50% of obesity
6. Expression of a designer receptor in specific neuronal cells (DREADD)	Muscarinic receptor in POMC neurons	Feeding when receptor activated by ligand

Further information on each of these examples can be found either in the text or in Reference [1].

obesity, indicating that these neurons only partially regulate the full effects of leptin on energy balance and suggest that leptin receptor activity in other brain regions is essential for the leptin effects on feeding behavior and metabolic rate. In contrast, leptin activation of POMC neurons is necessary for its ability to reduce glucose and insulin levels and to raise blood pressure [40].

Insulin, besides its role to control peripheral glucose homeostasis, also acts as a chronic feedback signal to the CNS on the level of body fat and energy stores, as does leptin. Such a role for insulin was initially promoted from ICV infusion studies which showed insulin could suppress food intake. However, it was the ability to knock out the insulin receptor in a tissue-specific manner that provided the conclusive evidence of this long-term role of insulin as a feedback signal regulating energy homeostasis. Mice with a neuronal specific loss of insulin receptors are hyperphagic and become moderately obese and have an attenuated ability to suppress hepatic gluconeogenesis [41]. This showed the importance of central insulin signaling to the regulation of peripheral metabolism. However, knockout studies can always be criticized for the potential changes that occur during development in the absence of the expressed gene, so the development of conditional knockouts or gene expression models has facilitated a clearer insight into the roles of specific genes in the growing or adult animals. One such example of this approach [42] compared two inducible knockouts of the insulin receptor that used the Cre-Lox system to produce mice that could knockdown IR expression through tamoxifen or doxycyclin treatment in either the whole body or just in peripheral tissues. By comparison of their responses, insight into the role of brain IRs was gained. These studies confirmed the importance of brain IR and central insulin signaling for the regulation of peripheral glucose homeostasis. Thus the roles of insulin to inhibit hepatic gluconeogenesis and glycogenolysis, to promote lipid deposition in adipose

tissue and to act as a CNS signal to regulate energy homeostasis and peripheral metabolism are confirmed through these models.

Further support comes from studies of *experimental models that have altered brain insulin sensitivity*. This can be illustrated by the studies on PKCθ, a serine kinase that prevents activation of insulin receptor substrate 1 (IRS-1) through phosphorylation and promotes internalization [43,44] and degradation of the insulin receptor [45]. The role of PKCθ in regulating energy balance and insulin sensitivity, however, is unclear at this time, as shown by numerous conflicting reports. PKCθ null mice are protected against the insulin resistance that is induced by acute infusions of lipids [46], and knockdown of arcuate PKCθ by injections of PKCθ shRNA reduces weight gain on a HFD [47]. However, PKCθ is required for the maintenance of muscle insulin sensitivity [48]. Likewise, our own studies on PKCθ null mice [49] identified an increased susceptibility to obesity and insulin resistance consistent with a previous report of the effects of transgenic muscle expression of a dominant negative PKCθ [48]. The differing observations may relate to acute versus chronic responses, the level of obesity, diet differences, or tissue-specific effects of PKCθ. In contrast, hypothalamic PKCδ has been shown to regulate hepatic glucose production and mediate the effects of peripheral lipid signals [50].

The role of PKCθ in the brain has received little attention. It is widely expressed within the CNS albeit at low levels [47,51] as PKCδ is the major isoform of PKC in neural tissues. Hypothalamic PKCδ has been shown to regulate hepatic glucose production and mediate the effects of peripheral lipid signals [50]. Nevertheless, knockdown of PKCθ in the arcuate nucleus with shRNA improved glucose tolerance in mice fed a HFD [47]. In our own studies, we have shown that PKCθ overexpression, induced by stereotaxic injections of a lentiviral-PKCθ construct into the central nucleus of the amygdala, induces

insulin resistance in that region. Chronically, this is associated with a small increase in food intake, increased body weight and body fat, the development of hepatic insulin resistance and increased hepatic triglyceride levels while conversely, the hypoglycemic response to insulin is increased and the glucose tolerance is improved suggestive of increased peripheral sensitivity [52,53]. This is a distinctly different phenotype from that induced by hypothalamic insulin resistance. Insulin acts in the hypothalamus to inhibit hepatic glucose production [54] and fatty acid activation of hypothalamic PKCθ suppresses this effect [47]. Intracerebroventricular (ICV) injections of PKCθ, which increased the expression of PKCθ in the arcuate nucleus, impaired glucose tolerance in our studies when rats are fed a HFD [52,53] consistent with a previous report that arcuate injections of PKCθ shRNA improved glucose tolerance [47]. This suggests that developing insulin resistance in the hypothalamus is associated with peripheral insulin resistance and/or increased hepatic glucose production whereas insulin resistance in the CeA is associated with improved glucose clearance. The lipid phenotype also differs between these two models with hepatic hypertriglyceridemia and normal serum triglycerides with CeA insulin resistance and normal liver lipids but increased serum triglycerides associated with hypothalamic insulin resistance.

Since insulin receptors are widely distributed in the CNS, we should be careful not to assume that all of the metabolic changes associated with central insulin activities are reflective of actions solely in the hypothalamus. The suggested role of the amygdala in regulating peripheral glucose and lipid metabolism is supported by recent reports that the medial amygdala contains glucose-sensing neurons that appear to innervate the VMH through Urocortin 3 neuronal connections [55].

Tissue-targeted knockout or knockdown of insulin receptors

Tissue-targeted knockout or knockdown of insulin receptors has not only provided profound new insight into the regulation of peripheral metabolism but has identified the importance of tissue cross-talk. This tissue-targeted gene knockout is achieved by using tissue-specific gene promoters to regulate Cre expression (Figure 35.1). Targeting hepatic insulin receptors using the albumin promoter to drive Cre expression led to a diabetes model with increased gluconeogenesis and hepatic insulin resistance and very elevated insulin levels that result from reduced hepatic clearance of insulin and increased secretion. Insulin normally activates multiple signaling pathways within the liver. Conventionally, it would have been necessary to have selective specific inhibitors of these individual signaling pathways to identify the specific roles of each. However, we now use genetic targeting for studies which will identify the role of specific signaling pathways. Thus knockout of *FOXO1* reversed most of the metabolic changes associated with liver specific knockout of *INSR*, *IRS-1*, or *IRS-2* genes. Such data was used to support the concept that insulin stimulated Akt signaling inhibited gluconeogenesis through suppression of *FOXO1* gene expression [56]. This has been investigated further by Lu and colleagues [57] using double knockouts of *Akt1/Akt2*, and *FOXO1* providing additional insight into the regulation of hepatic metabolism during fasting and refeeding.

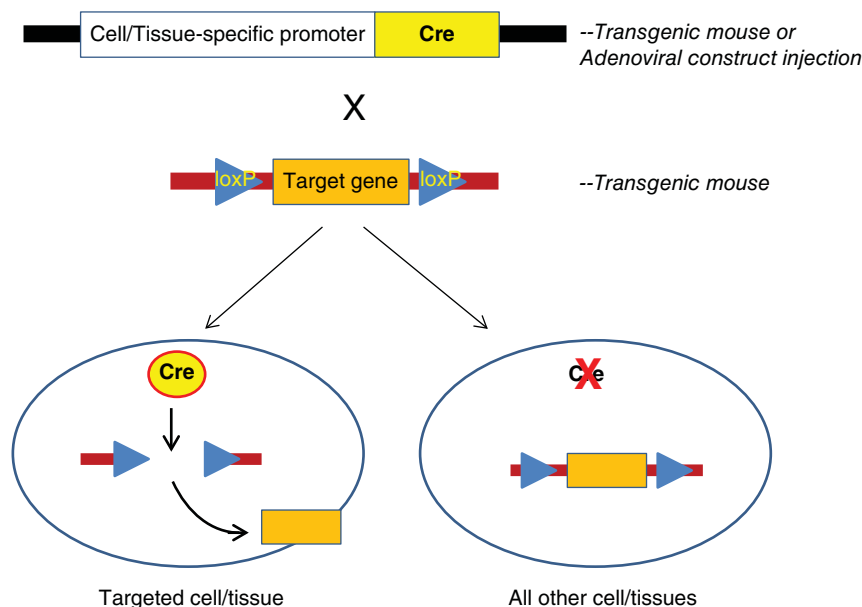
Tissue-targeted knockouts of the insulin receptor have been particularly informative. These have been reviewed previously in detail [58]. Loss of adipose tissue (both white and brown) insulin receptors led to a lean mouse that was resistant to the development of obesity from dietary or hypothalamic manipulations while maintaining normal glucose tolerance,


Figure 35.1 The Cre/Lox system for tissue or cell specific gene knock out.

suggesting that adipose tissue is not a major site for glucose clearance. In contrast, specific knockout of insulin receptors in brown adipose tissue using the UCP1 driven Cre expression leads to an age-dependent loss of BAT and, surprisingly, hyperglycemia associated with a loss of β-cell function. Loss of insulin receptors in muscle using the Cre/lox system impaired insulin signaling and insulin-stimulated glucose uptake but did not result in whole body insulin resistance. However, the mice do become obese and hypertriglyceridemic as more glucose is partitioned to adipose tissue for lipogenesis. In contrast, targeted lifetime knockout of IR in the pancreatic β cells inhibits glucose-stimulated insulin secretion that was not present in mice with a conditional knockout in the adult animal, indicating the developmental importance of insulin signaling in the pancreas.

Tissue-specific gene manipulations have also illustrated the interdependence and cross-talk between tissues. Thus, an adipose tissue specific knockout of peroxisome proliferator-activated receptor gamma (*PPARγ*) impairs adipocyte proliferation and increases free fatty acid flux to the liver which becomes insulin resistant and exhibits enhanced gluconeogenesis and triglyceride deposition [59]. In contrast, transgenic expression of a dominant negative cAMP response element binding protein (*CREBP*) in adipose tissue protects the liver from the development of steatosis on a HFD and enhances insulin sensitivity during the development of obesity [60].

While gene knockout provides many informative models, *targeted gene rescue* in knockout mice has become a frequent approach towards "proof of function." An example of this approach by Balthasar et al. demonstrated that rescuing MC4R expression in the PVN of LoxTB-MC4R mice (which have deficiency of MC4R everywhere in the body) prevented 50–60% of the usual obesity associated with MC4R deficiency, and this was mostly mediated by a reduction in food intake since no effect on thermogenesis was observed [61]. Thus, MC4R activity in other brain regions regulates the melanocortin control of thermogenesis.

Finally, the "designer receptors exclusively activated by designer drugs (DREADD) technology" has been developed to facilitate the activation of specific neuronal subtypes. A mutated muscarinic G-protein coupled receptor, that is unable to bind native ligands but has a high potency for an otherwise inert pharmacologic ligand, can be targeted to specific neuronal subtypes expressing Cre recombinase using an adenoviral (AAV)-Cre-recombinase-dependent expression system that can be stereotaxically injected. Using this technology, Krashes et al. [62] injected an AAV-Cre recombinase expression-dependent mutated receptor vector into the arcuate nuclei of mice expressing Cre-recombinase in their AgRP neurons. Activation of these expressed receptors by injections of the pharmacologic ligand depolarized and activated the AgRP neurons and induced feeding behavior in a rapid and reversible manner. This DREADD approach will provide a series of new models that will facilitate the investigation of specific neuronal subtypes on both feeding behavior and peripheral metabolism.

Fatty acid binding proteins

Given the extreme rise in obesity over the past two decades there has been a significant increase in the elucidation of the pathways used by the body to recognize and respond to nutrients at sites from the oral cavity through the digestive and central nervous systems. Of particular recent interest has been the identification of the mechanisms that the body uses to detect dietary fat. The recent deorphanization of a number of G protein coupled receptors (GPCRs) has lent credence to the notion that free fatty acids appear to be important *primary* chemical messengers that signal the presence of dietary fat but the physiologic function of many of these receptors has not been clearly defined at this time. The major classes of free fatty acids have been identified as ligands for these receptors including the mono- and poly-unsaturated fatty acids (GPR120 [63] and GPR40 [64]), the medium chain saturated fatty acids (GPR84 [65]) and the short chain saturated fatty acids (GPR41/43 [66]). In addition to the fatty acid-activated GPCRs, the fatty acid binding protein CD36 has been proposed to play major roles in the transduction pathways for fatty acids in a variety of fat-responsive tissues [67] either as a fatty acid transporter, primary receptor or co-receptor working in concert with fatty acid-activated GPCRs [68]. Together, it is clear that there is a picture emerging that free fatty acids, present in food or generated via the action of a number of lipases, signal the presence of dietary fat.

Research showing the ability of free fatty acids to act as ligands at GPCRs has spawned numerous studies aimed at identifying a role for these receptors in normal physiologic processes. These proteins vary in their distribution, ligand specificity, and functional roles as summarized in Table 35.2. GPR120 appears to play critical roles in the ability to elicit chemosensory responses in both the taste system and the digestive system to mediate the ability of fatty acids to stimulate the release of satiety hormones like glucagon-like peptide 1 and cholecystokinin from the small intestine [69], and to play a role in high fat diet-induced adipogenesis [70]. A closely related GPCR that is also expressed in the intestine, GPR119, whose cognate ligands include polyunsaturated alkamides, may also play a role in the control of food intake [71]. GPR40 expression overlaps with that of GPR120 and includes the taste system, gut, liver, pancreas, and adipose tissue and has been most well studied for its role in fatty acid-induced stimulation of insulin release from pancreatic β cells and in inflammatory responses [72].

GPCR-mediated physiologic responses to fatty acids are not limited to the unsaturated fatty acids. Additional members of the GPR40-family of receptors include GPR41 (FFAR2) and GPR43 (FFAR3), which have similar, but not identical, tissue distributions and functions [66] (Table 35.2). GPR41/43 respond to the short chain saturated fatty acids (SCFAs; C2:0 through C6:0) and like other fatty acid-activated GPCRs have roles in the enteric nervous system. Significant interest has focused on the reported effects of SCFAs generated through the activity of gut microbiota to stimulate these receptors in the digestive system related to a

Protein	Expression	Ligands	Effects of gene knock out
GPR40	Tongue/gut/liver	MUFA/PUFA	
GPRs 41and 43	Enteric NS	SCFA C2-6	Reduced GLP-1 secretion Improved glucose tolerance
GPR84	Tongue	Saturated MCFA	
GPR120	Tongue/intestine	MUFA/PUFA	
CD36	Tongue/ intestine/ liver	All FA	Metabolic syndrome

number of functions including colonic contraction and intestinal anti-inflammatory responses [73] and in adipocytes where they contribute to SCFA-induced leptin release [74].

The fatty acid translocase, CD36, plays a critical role in the transport of long chain fatty acids across biologic membranes. While there a number of proteins in addition to CD36 that fulfill this function of fatty acid translocation in cells, CD36 appears to be of particular importance [75] for cell activation and the sensing of circulating fatty acid levels or fuel availability and to be the primary receptor for fat taste [76]. A link between CD36 function and obesity and metabolic syndrome [77–79] has been identified consistent with studies in human populations that appear to link variants in CD36 with differences in fatty acid sensing ability and, further, obesity [80].

In light of the described activities of these fatty acid receptive proteins, it is not surprising that a number of animal models have been developed to identify their causal link to nutrient-related diseases such as obesity and diabetes. With the exception of GPR84 where no direct link between activity at this receptor and obesity/diabetes currently exists, the other fatty acid receptive proteins have been implicated in these conditions. For example, the SCFA receptors, GPR41 and GPR43, which facilitate the role of SCFAs as endocrine regulators of metabolism may represent important targets for treatment of metabolic disorders (for review see [81]). Consistent with this interpretation, mice lacking GPR41 and GPR43 show reduced GLP-1 secretion and an impairment of glucose tolerance [82].

Like the fatty acid-activated GPCRs, by virtue of its function in fatty acid uptake, CD36 has similarly been shown to play important roles in metabolic regulation. Mice lacking CD36 have shown a host of physiologic challenges in a variety of tissues with many involving conditions related to metabolic syndrome and diabetes (for review, [83]). With respect to obesity and its health effects, it appears that the greater the expression of CD36 the greater the risk of obesity-related

complications [84–86]. This viewpoint is strengthened by recent studies showing the regulation of CD36 expression by HFD [87,88] in a manner consistent with this relationship.

Our understanding of the nature of fatty acid signaling and the cognate receptors for fatty acids in the central nervous system and periphery is far from complete. However, a picture is emerging that shows important roles for fatty acid receptors in normal physiology particularly in processes related to the control of food choice, food intake, and in the control of energy balance and normal metabolic processes. The development of further animal models targeting these fatty acid signaling/transporting proteins will be fundamental to the development of further insight to their physiologic roles.

In summary, the development of new genomic technologies has dramatically expanded the number of new animal models of obesity and T2DM. These have promoted new insight into the pathophysiology of the diseases as well as providing additional insight into the roles of specific genes and signaling pathways. Their application to genes more recently implicated in lipid signaling will facilitate our understanding of these genes. Together with the development of models that mimic human conditions and treatment approaches, the continued use of and development of new animal models is likely to provide a fuller understanding of the roles of individual genes and signaling pathways in the pathophysiology of obesity and T2DM. This, in turn, may help in the future development of new treatment and prevention approaches.

The role of the hypothalamus in the maintenance of energy balance and peripheral glucose control

Luis Varela[1] and Tamas L. Horvath[2]

[1] Program in Integrative Cell Signaling and Neurobiology of Metabolism, Section of Comparative Medicine, Yale University School of Medicine, New Haven, CT, USA

[2] Yale Program in Integrative Cell, Signaling and Neurobiology of Metabolism, New Haven, CT, USA

Key points

- The hypothalamic neuronal substrate of energy metabolism and glucose homeostasis is becoming clearer.
- Transcriptional regulators of AgRP and POMC neurons have been discovered and tied to leptin action.
- FOXO1 and mTOR are critical intracellular signaling molecules in hypothalamic regulation of feeding and glucose homeostasis.
- Different subpopulations of hypothalamic neurons respond to leptin and insulin.
- Regulation of feeding behavior and glucose metabolism do not always go hand-in-hand.

Introduction

Although obesity has only recently become one of the more important health problems of developed societies, it has been studied for centuries. Obesity is no longer looked at as just a major health problem but is considered an economic predicament as well—placing an enormous financial burden upon society for the care and treatment of patients. This metabolic state and its associated illnesses—such as diabetes mellitus, dislipidemia, and hypertension—have increased healthcare costs beyond sustainable levels. It has been calculated that over the next 20 years, the healthcare costs attributable to obesity will rise to about 16% of the total healthcare costs in Western countries [1,2].

Early attempts to understand the biologic and pathological aspects of obesity on the part of researchers have led to several observations. Several brain areas and factors are involved in the regulation of food intake and body weight as it relates to obesity. These studies found that the central nervous system (CNS), mainly the hypothalamus, plays a pivotal role in integrating signals from peripheral tissues—including the liver, white adipose tissue, gut, and so on—to regulate energy homeostasis (Figure 36.1). Secretions from these various tissues act as the peripheral signals that relay information regarding the energy status of the organism to the CNS, which integrates these signals and in turn regulates energy intake and expenditure. Two of the most well-known and studied peripheral signals are leptin and insulin, both of which are expressed in correlation with the total body fat mass [3]. In states of energy deficiency, the blood levels of these two molecules are lower, while in states of energy surplus, they are increased.

Earlier publications reported that pituitary adenomas cause obesity [4,5]; however, current reports using more innovative methods and novel techniques reveal that the hypothalamus is the major regulator of feeding. Efforts to understand the basis of obesity focused on it and its modulation by peripheral signals. The first clues about the importance of the hypothalamus in the control of feeding were given by different studies showing that hypothalamic lesions cause alterations in food intake and body weight [6–9]. The hypothalamus, located in the mediobasal part of the brain, is organized into well-structured nuclei (ventromedial (VMH), paraventricular (PVH), lateral (LHA), and so on). Within each nucleus are different neuronal populations characterized by the various neuropeptides that are expressed; these neuropeptides are involved in the control of food intake. For instance, it has been observed that lesions in the VMH are associated with hyperphagia [9], while lesions in the LHA cause hypophagia and a decrease in body weight [8]. Within the basal part of the hypothalamus is located the Arc, where the blood–brain barrier has a special modification to allow the entry of nutrients, hormones, and other molecules from the blood. Its privileged location allows it to be the first sensor of peripheral signals [10]. Because of this, it has been postulated that the Arc plays a fundamental role in sensing
Figure 36.1 Hypothalamic leptin and insulin signals regulate several peripheral functions. Leptin and insulin secreted by white adipose tissue (WAT) and pancreas, respectively, inform the hypothalamus about the energy status of the organism. When LepR-b and InsR are activated by these hormones, they promote changes in hypothalamic neuropeptides which cause alterations in peripheral functions to restore energy balance and glucose metabolism.

the global energy status of the organism [10]. Within the Arc reside two different neuronal populations characterized by the expression of specific neuropeptides which have potent effects on energy homeostasis [11]. One of these populations consists of the pro-opiomelanocortin/cocaine-amphetamine-regulated transcript (POMC/CART) neurons which mediate strong anorexigenic effects; excitation of these neuropeptides decreases food intake and body weight. On the other hand, the second population of AgRP/NPY neurons has a potent orexigenic effect; their excitation increases food intake. Thus, in a situation of negative energy balance, for example fasting, the expression of AgRP is increased, and POMC expression is decreased. In contrast, during a state of energy surplus, AgRP levels are diminished, while POMC levels are elevated.

Leptin and insulin signaling pathways in the hypothalamus

Leptin, an adipokine, is secreted by white adipose tissue (WAT) in positive relation to the total amount of body fat in all species so far studied. Insulin is secreted by the pancreatic β cells, which are sensitive to the blood glucose level in the short term and the level of adiposity in the long term. Both peripheral signals can induce a strong anorexigenic effect [3]. Central administration of these molecules, which mimics a state of energy surplus, inhibits food intake and decreases body weight [12]. Furthermore, their central actions have a potent impact in regulating glucose homeostasis and lipid metabolism. The actions of leptin and insulin are mediated by the receptors LEPR-b and InsR,

respectively. These receptors are widespread and are present in several areas of the CNS. Different studies have shown particularly significant expression in the hypothalamus, with higher expression in the AgRP and POMC neurons of the Arc. Given the role of these neuronal populations and the demonstration of LepR and InsR within them, it was proposed some years ago that the leptin and insulin signaling pathways in the POMC and AgRP neurons of the Arc are highly significant in the regulation of food intake, body weight, and glucose homeostasis.

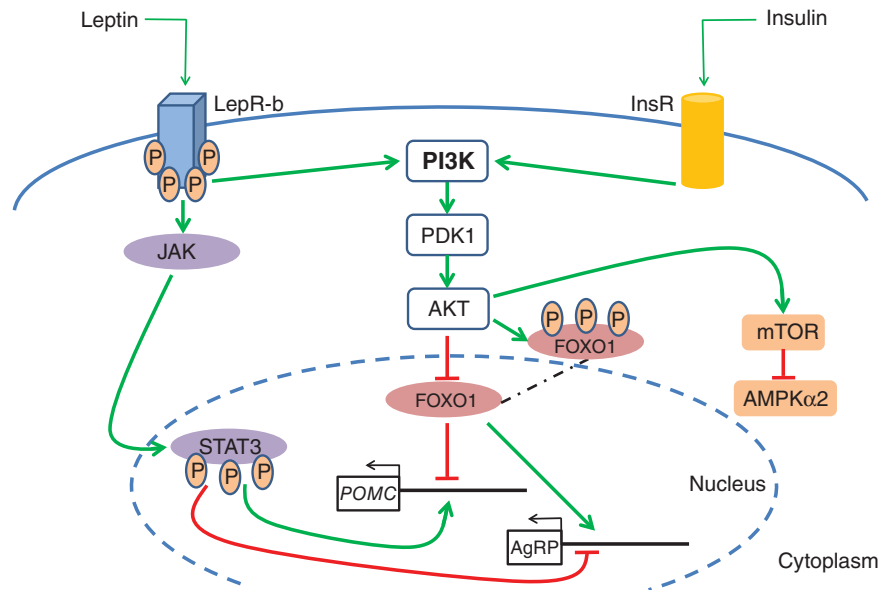
Leptin activates different signaling cascades assessed in culture as well as whole animal models (Figure 36.2). When this hormone binds the extracellular domain of LEPR-b, it recruits and activates the Janus kinase (JAK) pathway. JAK binds and phosphorylates LEPR-b [13], which activates STAT3 (Figure 36.2). Once phosphorylated, STAT3 binds to *POMC* and *AgRP* promoters, stimulating POMC expression and inhibiting AgRP expression [14,15]. In recent years, the most studied targets of leptin action are the proteins involved in the PI3K signaling pathway. Leptin activates PI3K, which induces the synthesis of PIP_3 from PIP_2 [16–18]. Accumulation of PIP_3 leads to PDK1 activation and thus, activates protein kinase B (PKB, also known as AKT) (Figure 36.2). Interestingly, the insulin signaling pathway converges with the leptin pathway as PI3K is activated by both to modulate body weight and glucose homeostasis [19,20]. AKT, one of PDK1's downstream targets, plays an important role in the regulation and activation of a great number of proteins and transcription factors, including FOXO1 [21,22], AMPK [23,24], and mTOR [25]. FOXO1 acts as an inhibitor of expression of POMC [26]. When leptin and/or insulin phosphorylates this transcription factor, it induces its


Figure 36.2 Leptin and insulin signaling pathways in the Arc. Signal transducer and activator of transcription 3 (STAT3) is activated and phosphorylated when leptin binds LepR-b. p-STAT3 binds to *POMC* and *AGRP* promoters, stimulating POMC expression and inhibiting AgRP. Leptin and insulin signaling pathways converge in phosphatidylinositol-3-kinase (PI3K). Activation of PI3K leads to activation and phosphorylation of Forkhead box protein O1 (FOXO1), a repressor of POMC expression. Phosphorylation of FOXO1 provokes its nuclear export and allows STAT3 binding to *POMC* and *AgRP* promoters.

nuclear export, thus allowing the binding of STAT3 to the *POMC* promoter to induce its expression. In AgRP neurons, the nuclear export of FOXO1 abrogates mRNA expression, because in this case, STAT3 is able to bind the *AgRP* promoter and impair transcription [27].

Leptin and insulin regulate the AMPK signaling pathway in the hypothalamus [24]. Proteins involved in this pathway sense the global energy status and are activated by an energy deficiency [23,28]. Leptin and insulin inhibit the activation of AMPK and its downstream targets, thereby signaling energy surplus. The mTOR pathway, closely related to AMPK, plays an important role in the hypothalamic regulation of food intake, sensing nutrient availability and the energy status [25,29]. In contrast to AMPK, mTOR expression is higher in situations of energy surplus [25]. Thus, it has been reported that intracerebroventricular (ICV) leptin administration increases mTOR expression [25]. Indeed, mTOR plays an important role as a mediator of leptin action in the hypothalamus: it has been demonstrated in rodents that an intact mTOR signaling pathway is necessary to maintain the anorexigenic effects of leptin [25].

Hypothalamic leptin and insulin mediate food intake, energy expenditure, and glucose homeostasis

Leptin in POMC and AgRP neurons

For a number of years, it has been known that leptin and insulin play important roles in the regulation of energy

homeostasis [30]. In mice, mutations of leptin (Lep[ob/ob]) or LepR (Lep[db/db]) are associated with increased body weight and impaired glucose homeostasis (hyperglycemia, hyperinsulinemia, insulin resistance, impaired hepatic glucose production, and so on) [31–33]. It has been reported that ICV leptin injections in these mice reduce body weight and food intake, and ameliorate glucose metabolism [12]. It is expected, then, that obese patients would present lower serum leptin levels, but surprisingly, the opposite is true—high levels are expressed. This is believed to be the consequence of the so-called leptin resistance, a state in which leptin signaling is impaired and the body compensates by producing excess leptin [34,35]. These findings, together with the evidence that the Arc neurons are very important in the regulation of energy balance, focused attention on the POMC and AgRP neurons as the major targets of leptin action. It has been reported that leptin action depolarizes (activates) POMC and hyperpolarizes (inhibits) [36] AgRP neurons [37].

There were many attempts to investigate the exact mechanism by which these hormones act in the hypothalamus. Following the discovery and use of Cre/Lox technology, the mechanisms of action of both hormones have become better understood but are still unclear. The deletion or overexpression of LepR in POMC or AgRP neurons causes changes in body weight, food intake and glucose homeostasis [38–42]. Thus, the importance of POMC in leptin signaling has been intensely studied. Currently, it is well known that POMC neurons are essential in mediating leptin actions in the brain. Several animal studies have shown that deletion of LepR in these neurons promotes obesity without changes in food intake or energy expenditure

[38–40,42] and that overexpression of this receptor in POMC neurons of LepR-null mice partially rescues the obesity and hyperphagic phenotype characteristic of this mouse strain [39,43]. Despite this, there are controversies about the role that POMC plays in leptin signaling. Two different reports have suggested two different reasons for the decrease in body weight seen in LepR-null mice that re-express LepR in POMC neurons. One report states that it is due to diminished food intake [39] while the other attributes it to increased energy expenditure [43]. In the latter, the authors postulated that this discordance could be due to differential LepR expression in different subsets of POMC neurons, and that the effects of leptin outside of the Arc are important for the proper regulation of food intake. In both animal models, re-expression of LepR improved glucose levels and insulin sensitivity independently of body weight, indicating that leptin signaling in POMC neurons plays a key role in regulating glucose homoeostasis [42,43]. The effects of leptin on AgRP neurons, however, are not as clear. In these neurons, the deletion of LepR is associated with an increase in total body weight and adiposity [44]. AgRP and POMC are both involved in the maintenance of energy balance by leptin signaling. Mice with ablation of LepR in both the POMC and AgRP neurons present more severe obesity [40]. It has been postulated that these subsets of neurons work in a synergistic way to respond to leptin [40].

Insulin in POMC and AgRP neurons

Insulin, like leptin, has been demonstrated to be an important regulator of energy regulation via the CNS [45–48]. It has been demonstrated that central insulin administration regulates feeding behavior. Since the first evidence demonstrating that brain-specific deletion of InsR (NIRKO mice) is associated with obesity and increased food intake [45], a huge number of reports have tried to identify the neurons and mechanism through which this hormone affects the brain. In these NIRKO mice, obesity is related to high leptin levels [45], demonstrating that central leptin actions require intact insulin signaling in the CNS. Furthermore, central insulin is essential for the regulation of proper glucose homeostasis. As in the case of leptin, POMC and AgRP neurons are supposed to be critical targets of the insulin signaling pathway. It has been shown that insulin acts on these subsets of neurons, as evidenced by the fact that its central administration provokes hyperpolarization of POMC and AgRP neurons in the Arc [20,24,40,49]. Curiously, unlike leptin, the selective ablation of InsR in POMC or AgRP neurons has no effect on body weight or food intake [20]. Similar to previous pharmacologic reports, transgenic deletions of InsR in POMC and AgRP neurons have an impact on glucose metabolism. Specifically, similar to pharmacologic blockade of insulin signaling, mice with ablation of InsR in AgRP (but not in POMC) neurons have impaired suppression of hepatic glucose production (HGP) [20], demonstrating the significance of insulin action on these neurons in the maintenance of glucose homeostasis.

To further investigate the role of Arc neurons in mediating the effects of insulin, one work has analyzed the effects of InsR re-expression in AgRP and POMC neurons in mice lacking InsR expression in the Arc [50]. In accordance with previous reports, these InsR knockout mice showed a potent suppression in HGP when InsR is re-expressed in just the AgRP neurons [50]. In contrast, re-expression in the POMC neurons had no effect on HGP, but surprisingly, these mice have impaired glucose homeostasis compared to the InsR mice [50]. Contrary to other reports, POMC neurons seem to play a role in energy homeostasis through insulin signaling. POMC knockin mice show increased food intake and locomotor activity [50]. Taken together, these results demonstrate that AgRP neurons mediate many of insulin's effects on glucose homeostasis and that other neuronal populations in different hypothalamic nuclei—such as VMH, for example—are also likely involved in the regulation of body weight and food intake.

Leptin's and insulin's mechanisms of action in regulating energy and glucose homeostasis

After the Arc POMC and AgRP neurons were identified as central mediators of leptin and insulin actions, several reports tried to understand the exact mechanisms through which these hormones modulate energy and glucose homeostasis. As stated earlier, leptin and insulin are involved in the activation of different signaling pathways. Genetic modifications in these target genes have provided some clues about how both hormones are able to trigger responses by the POMC and AgRP neurons. For instance, after STAT3 deletion in the CNS was found to induce an obese phenotype associated with lower mRNA levels of POMC, this gene was studied as an important factor involved in leptin signaling [51,52]. Various work in which STAT3 was deleted or overexpressed in Arc neurons demonstrated a clear role of this protein in this mechanism [14,15,53]. In POMC neurons, it has been found that STAT3 activation causes mild obesity associated with increased food intake and lower *POMC* mRNA levels [15], which is in agreement with the stimulatory effect of STAT3 on POMC expression mentioned earlier. Furthermore, this animal model exhibits an impaired leptin response. Peripheral leptin administration was unable to reproduce the expected effects on body weight and food intake seen in control mice, an observation that reinforces the importance of STAT3 signaling in POMC neurons regulating leptin effects [15,53]. In addition to leptin resistance, constitutive activation of STAT3 in POMC neurons leads to insulin resistance [15], which is probably mediated by an increased expression of suppressor of cytokine signaling 3 (SOCS3; an inhibitor of leptin signaling). This study confirms the role of STAT3 as a mediator of not only leptin, but also insulin signaling in POMC neurons.

The role of STAT3 in AgRP neurons has also been examined [14,26,54]. Its activation by leptin has inhibitory effects on

AgRP mRNA levels. As expected, and because of the findings showing that STAT3 expression modifies AgRP expression [26], constitutive activation or deletion of STAT3 in this neuronal population regulates energy balance [14,55]. STAT3 deletion on AgRP neurons leads to a mild gain in body weight, and unlike the POMC neurons, this deregulation is due to effects on energy expenditure [55]. Overexpression of STAT3 in AgRP neurons is associated with increased locomotor activity, with no effects on food intake [14]. This is consistent with the recovery of locomotor activity after restoration of leptin levels in LepR knockout mice [14,56]. Furthermore, STAT3 has the effect of ameliorating impaired glucose homeostasis on mice exposed to a high-fat diet (HFD) [14], indicating the important role that STAT3 has in mediation of leptin effects. Altogether, these reports provide a clear implication that STAT3 is involved in the mechanism(s) by which leptin and insulin elicit responses by the POMC and AgRP neurons. Interestingly, overexpression of STAT3 in each separate neuron population results in different effects on energy balance and glucose homeostasis, indicating that synergy between the groups of neurons is necessary for a complete and appropriate response to leptin.

The PI3K/PDK1/FOXO1 signaling pathway acts to integrate leptin and insulin signals. The primary effector of this pathway, PI3K, has been shown to be a mediator of both hormones. PI3K is required for the actions of leptin and insulin to activate or inhibit POMC and AgRP neurons [18,20,24,37]. It has been demonstrated that the PI3Kp110β subunit has a fundamental role in regulating body weight, food intake, and glucose homeostasis through leptin and insulin signals [57]. Once more, attention has focused on the importance of PI3K in mediating the effects of both hormones; it became obvious that the mechanisms through which PI3K provokes changes in energy homeostasis were not clearly identified. Several studies report the main PI3K target in affecting energy homeostasis is PDK1. Recently, it was demonstrated that PDK1 is involved in regulating the ability of POMC and AgRP neurons to sense leptin and insulin inputs [17,58,59]. In POMC neurons, the deletion of PDK1 in mice promotes a gain in body weight associated with increased food intake [17,58]. As expected, mice with this ablation exhibit lower *POMC* expression [17,58], which is responsible for the changes in food intake seen in these animals. Furthermore, PDK1 deletion in POMC neurons affects glucose homeostasis. Administering leptin to these animals cannot reproduce the body weight loss provoked in control mice, suggesting that leptin action in POMC neurons is dependent upon PDK1 [58]. As this pathway plays an integrative role in leptin and insulin transduction signaling, it has been reported that PDK1 is involved in insulin action, too. The lack of PDK1 in POMC neurons leads to increased insulin sensitivity in adult mice and higher blood glucose levels in young and obese mice [17]. The deletion of PDK1 in this neuronal population has no effects on energy expenditure. On the other hand, in AgRP neurons, PDK1 was shown to regulate energy balance by provoking changes in food intake and energy expenditure [59].

As anticipated, and contrary to POMC effects, the deletion of PDK1 in the AgRP population promoted body weight loss as a consequence of diminished food intake and enhanced energy expenditure—specifically increased locomotor activity [59]. In addition, these mice were more sensitive to leptin. Chronic peripheral administration of leptin induced greater reductions in body weight and food intake [59]. PDK1 acts by activating AKT and by regulating many kinases and transcription factors. One of the most studied of these is FOXO1, which has been involved in hypothalamic neuropeptide expression and food intake. As stated above, when FOXO1 is activated by leptin in POMC neurons, it promotes POMC transcription [26], but conversely in AgRP neurons, it inhibits neuropeptide expression [27]. As expected, previous data from the two PDK1 knockout (KO) models described earlier are in agreement with FOXO1's effects on feeding. PDK1 deletion in POMC neurons impairs FOXO1 phosphorylation, and thus, this transcription factor remains in the nucleus to inhibit POMC expression [17,58]. In AgRP neurons, PDK1 ablation leads to nuclear accumulation of FOXO1, thereby decreasing food intake [59]. This data indicates that FOXO1 could be the terminal effector regulating leptin signaling; in fact, in these studies stimulation of FOXO1 rescues the phenotype. Its activation in PDK1$^{\Delta POMC}$ mice abolished this change in body weight, POMC expression and glucose homeostasis [17,58]. In AgRP neurons, FOXO1 activation, which leads to its exclusion from the nucleus, rescuing the phenotype seen in the AGRP:PDK1KO mice [59]. These studies emphasize the importance of FOXO1 as a regulator of leptin and insulin actions.

Several studies have described the specific action of FOXO1 in the regulation of food intake, energy expenditure, and glucose homeostasis. FOXO1 is a transcription factor that plays a role in regulating glyconeogenesis and glycogen breakdown. Leptin and insulin require FOXO1 signaling in the Arc to provoke their anorexigenic effects, and that leads to increased leptin and insulin plasma levels. Given these clues, the role of FOXO1 in POMC and AgRP neurons was investigated [22,26,60,61]. In POMC neurons, the deletion of FOXO1 leads to body weight loss associated with decreased food intake [60]. This change in feeding behavior is not associated with changes in *POMC* expression, but the authors linked it with increased levels of α-melanocyte-stimulating hormone (α-MSH), a proteolytic product of POMC, and they found that FOXO1's actions on energy balance are mediated by carboxy peptidase E (CPE), a prohormone processing convertase [60]. No changes in energy expenditure were found in this model. Furthermore, FOXO1 expression in POMC neurons plays an important role in leptin and insulin action [60,61]. The deletion of this transcription factor in this POMC neuron increased leptin sensitivity [60]. Recently, an elegant report investigated the role of FOXO1 in AgRP neurons [22], demonstrating that FOXO1 signaling is required in AgRP neurons in order to regulate energy homeostasis. The specific ablation of FOXO1 in this neuronal population was associated with decreased food intake

and locomotor activity [22]. Interestingly, body weight was not affected. In addition, it has been shown that a lack of FOXO1 in AgRP neurons affects glucose homeostasis. This animal model presents altered HGP due to enhanced insulin sensitivity in the AgRP neurons [22]. In this work, G protein-coupled receptor 17 (Gpr17) was identified as the downstream target through which FOXO1 affects energy homeostasis in the AgRP neurons [22].

Summarizing, the individual contributions of the most important factors of leptin and insulin signaling transduction pathways have been described. STAT3 and FOXO1, the final targets of both pathways are shown to play key roles in energy balance and glucose homeostasis and can act independently within either the POMC or AgRP neurons in the Arc. In spite of this, any of these factors are able to regulate the total overall effect of leptin and insulin with regard to: food intake, energy expenditure, or glucose metabolism. This indicates that there must be a cooperative and synergistic interaction between pathways in order to elicit responses by the AgRP and POMC neurons to mediate anorexigenic effects.

On the other hand, mTOR is a downstream target of the PI3K pathway, and its activation is dependent upon nutrient availability [25,29]. In addition to its role to sense glucose and leucine levels, it has been shown that this pathway mediates the anorexigenic effects of leptin [25,62,63]. Pharmacologic studies have demonstrated that mTOR inhibition by rapamycin blunts leptin effects on food intake [25]. Furthermore, these results were corroborated by other reports using transgenic models. Mice with a selective lack of S6K were unable to respond to leptin treatment, showing that this pathway is involved in the mechanism which leads to leptin resistance [63]. The activation of the mTOR pathway in POMC neurons attenuates body weight loss and decreases food intake after leptin treatment [64]. This data supports the idea that the mTOR pathway is an important mediator of the onset of leptin resistance. As stated earlier, AMPK mediates leptin action, and is inversely regulated by mTOR. A recent report demonstrated that leptin action on the AMPK pathway is dependent upon mTOR [65]. Leptin-mediated activation of mTOR promotes inhibition of the AMPK pathway and thus regulates feeding behavior [65]. This novel mechanism accentuates the importance of the mTOR pathway in mediating the effects of leptin.

Hypoxia inducible factor (HIF), closely related to mTOR, is a heterodimer formed by α and β subunits. Meanwhile the β subunit is constitutively expressed, the α subunit is modulated by oxygen availability. Under hypoxic conditions, HIFα is stabilized, and under normoxia, it is degraded [66,67]. It has been demonstrated that this transcription factor is involved in the control of glucose metabolism [68]. The deletion of HIF in POMC neurons curtails the changes on POMC expression caused by glucose injection, demonstrating that HIF mediates glucose action on POMC neurons [68]. Leptin's effects are independent of HIF. AMPK and mTOR are nutrient sensors [23]. The activation of HIF prevents the effect on food intake provoked by AICAR, an AMPK activator. In the same

way, the orexigenic effects of rapamycin are blocked by HIF activation [68]. Furthermore, decreased food intake caused by the activation of mTOR in the mediobasal hypothalamus is reduced in mice lacking HIF in their POMC neurons [68]. This report shows a potent action of HIF in glucose sensing, and that this effect is mediated in POMC neurons through the involvement of AMPK and mTOR signaling [68]. However, the role of HIF is not only in glucose sensing. In the same report, the authors propose that HIF acts as a therapeutic target to oppose obesity. The animal model used in this study is more sensitive to HFD; however, the constitutive activation of HIF protected these mice against diet-induced obesity [68].

Potential role of autophagy in leptin's and insulin's mechanisms of action

Macroautophagy (referred to as autophagy) is a novel mechanism involved in the maintenance of cellular homeostasis and it may also be involved in the mechanism of action for leptin. Autophagy is a process whereby cytoplasmic organelles are sequestered and delivered into lysosomes for degradation [69]. Although the role of autophagy has been tested in other tissues [70,71], this mechanism has only recently been studied in the hypothalamus. In the last year, some reports have suggested that autophagy plays a role in the regulation of food intake [69,72,73]. Mice that lack *Atg7* (autophagy-related gene 7) selectively in POMC or AgRP neurons show altered energy homeostasis. In AgRP neurons, inhibition of autophagy promotes body weight loss associated only with increases in locomotor activity. In turn, they have a reduced rebound effect on food intake after fasting, indicating perhaps that these mice develop enhanced leptin sensitivity [69]. The deletion of *Atg7* in POMC neurons leads to obesity, and changes in food intake and energy expenditure [72], supporting the idea that autophagy regulates energy homeostasis. In agreement with the findings in AgRP neurons, the inhibition of autophagy in POMC neurons provokes potent effects in glucose homeostasis. These mice exhibit leptin resistance, and this is related to the inability of leptin to activate and phosphorylate STAT3 [73]. Furthermore, the lack of *Atg7* in POMC neurons increased blood glucose levels despite elevated insulin concentrations, indicating that these mice develop insulin resistance [72]. This data clearly demonstrates that autophagy plays a role in glucose homeostasis. In spite of this, the mechanism through which autophagy affects energy balance is still unknown; it has been proposed that the mTOR pathway can act to mediate autophagy-dependent changes in energy homeostasis [69,72].

In conclusion, in recent years, the individual contribution of each significant component of the JAK/STAT3 and PI3K pathways in the regulation of energy balance and glucose homeostasis has been described. Furthermore, studies of STAT3 and FOXO1, the terminal effectors of these pathways, have shown that they play vital roles in leptin and insulin actions. The POMC and AgRP neurons of the Arc of the hypothalamus have been identified as key central targets of leptin and

insulin action. New targets, such as mTOR, have been detected to be potent mediators of leptin and insulin signaling, and new mechanisms, such as autophagy, have been discovered to be involved in energy and glucose homeostasis. Despite this, more efforts are needed to understand the individual contribution of each factor discussed here and the global mechanisms by which they operate with the ultimate goal of obtaining a comprehensive understanding of leptin and insulin resistance. This would thereby advance the development of future therapeutic treatments to combat obesity and its associated metabolic syndrome.

SECTION VII

Clinical trial evidence in diabetes

Prevention of type 1 diabetes

Jay S. Skyler

Division of Endocrinology, Diabetes, & Metabolism, Diabetes Research Institute, University of Miami Miller School of Medicine, Miami, Florida, USA

Key points

- Type 1 diabetes (T1DM) is a progressive disease with genetic predisposition.
- T1DM is characterized by immunologically mediated β-cell destruction.
- Immune intervention studies have been conducted in recent-onset T1DM in an effort to interrupt the disease process and hinder the anticipated progressive decline in β-cell function.
- Some interventions have shown at least transient effect in recent-onset T1DM.
- Immune intervention studies have also been conducted in individuals at risk of T1DM in an effort to interrupt the disease process and prevent progression to clinical T1DM.
- No prevention study, as yet, has been unambiguously successful.

Introduction

Type 1 diabetes (T1DM) occurs when there is sufficient reduction of β-cell mass and function to require insulin therapy to control glycemia. Since the early 1970s, when islet cell antibodies (ICA) were first noted [1], and an association with human leukocyte antigen (HLA) was first described [2], T1DM has been characterized as a distinct disease from type 2 diabetes (T2DM). It the 1980s, Eisenbarth characterized T1DM as a slowly progressive disease that had a genetic predisposition and was characterized by immunologically mediated β-cell destruction [3]. This was certainly consistent with spontaneous diabetes in two animal models, the BioBreeding (BB) rat [4] and the nonobese diabetic (NOD) mouse [5]. Over the years, multiple studies in these rodent models have shown that diabetes can be prevented or stabilized by a vast variety of immunologic approaches [6]. This has led to multiple studies in human beings using immune interventions designed to prevent T1DM or to slow the decline in β-cell function characteristic of the disease process. This chapter summarizes the human studies that have been conducted, focusing in particular on randomized controlled clinical trials.

Most studies have been conducted in people with recently diagnosed T1DM, in an effort to preserve β-cell function. The earliest studies used clinical "remission" (variously defined) as the primary outcome measure. Most studies in the past two decades, however, have used as the primary outcome measure stimulated C-peptide as an index of β-cell function, usually in response to a standardized meal ("mixed meal tolerance test" (MMTT)), although some have used C-peptide response to glucagon administration ("glucagon stimulation test" (GST)). One study ambitiously used as its primary outcome measure C-peptide response during a hyperglycemic clamp followed by a GST.

Studies in established T1DM

Although prevention of T1DM is the logical ultimate goal of immune intervention studies, most studies to date have been conducted in recent-onset T1DM in an attempt to impede the disease process and preserve β-cell function. The first such attempt at immune intervention in T1DM was a study conducted in the late 1970s [7]. Multiple groups then tested a variety of approaches, most of which were not randomized controlled trials, and even those that were randomized were so small that there were insufficient numbers of subjects for valid conclusions [8,9]. Many early studies used either no control subjects, historical comparison groups, or concurrent nonrandomized comparison groups.

A pilot study, led by Calvin Stiller, and published in *Science* in 1984 [10], stimulated the development of multiple studies evaluating the effects of the immunosuppressive drug cyclosporin in T1DM [11–13]. Cyclosporin is a calcineurin inhibitor that interferes with the activity and growth of T-lymphocytes. Two large randomized controlled clinical trials—one from the French Cyclosporin Study Group [11] and the other from the

Canadian-European Cyclosporin Study Group [12]—were the first adequately powered studies to be conducted, and both showed that cyclosporin, continuously administered for 12 months, resulted in an increased proportion of subjects undergoing "remission" [11,12]. A small study conducted simultaneously demonstrated that cyclosporin resulted in preservation of C-peptide with a MMTT, but not with either a GST or intravenous glucose [14]. In an uncontrolled study in children, cyclosporin use was continued until remission was lost, and suggested that the early beneficial effects were not sustained [13]. This observation, together with the risk of cyclosporin-induced nephropathy [15], led to abandonment of cyclosporin as a clinical intervention for T1DM. Nonetheless, the studies clearly demonstrated that T1DM may be amenable to immune intervention.

During the 1980s and 1990s, several other interventions were evaluated. Three studies were conducted using azathioprine, an immunomodulatory drug inhibiting purine synthesis [16–18]. One of these used azathioprine together with glucocorticoids [16]. None of the three studies showed convincing results that might have stimulated the field. Another study was conducted with linomide, an immunomodulatory drug inhibiting pyrimidine synthesis [19]. In this randomized controlled trial, there was improvement in the GST in those subjects who had detectable residual β-cell function at entry. Two randomized controlled trials were conducted by vaccination with BCG (bacillus Calmette-Guérin strain of *Mycobacterium bovis*) [20,21]. These failed to demonstrate a beneficial effect on stimulated C-peptide, and in the larger study, there was a trend toward a more rapid decrease in C-peptide levels in BCG-treated subjects [21]. Oral insulin was also used in three studies in recent-onset T1DM, all essentially without beneficial effect [22–24]. Two small pilot studies reported in the early 1990s were the first to use monoclonal antibodies in an attempt to alter the course of T1DM, one using an anti-CD5-immunotoxin [25] and the other using an anti-CD4 [26]. These heralded the testing of two anti-CD3 monoclonal antibodies, which have been used in multiple controlled clinical trials.

Several studies have been conducted with anti-CD3 monoclonal antibodies, which target T-lymphocytes, particularly CD4-T-lymphocytes, but with relative sparing of T-regulatory cells. Two anti-CD3 antibodies have been used—teplizumab and otelixizumab [27–35]. The course of treatment was just 14 days for teplizumab and 6 days for otelixizumab. The phase 2 studies with both drugs showed beneficial effect on C-peptide [27–29], with effects sustained for 2 years after the initial treatment [28]. With otelixizumab, beneficial effects on A1c and insulin dose were seen as long as 4 years after the initial 6-day treatment course, although C-peptide response was not measured at that time [30]. Unfortunately, the phase 3 studies did not meet their primary outcome criteria. For teplizumab, the primary outcome was the combination of HbA1c <6.5% and insulin dose <0.5 units kg^{-1} day^{-1}, a dichotomous measure which was arbitrarily chosen [31]. Yet, when C-peptide was examined there was evidence of efficacy both at 1 year [31] and

at 2 years [32] following 14-day courses of teplizumab at entry and at 26 weeks into the study. For otelixizumab, the phase 3 study used a dose that was one-sixteenth (total of 3.1 mg over 8 days) of that used in the phase 2 study (total of 48 mg), in an effort to avoid any side effects [33]. Not only were side effects obviated, but so was efficacy. As a consequence, a formal dose-ranging study (NCT02000817) is currently underway in Belgium, using doses of 9, 18, 27, and 36 mg over 6 days.

There have been two other anti-CD3 studies with teplizumab. In one, the DELAY trial, rather than enrolling subjects with recent-onset T1DM, subjects with T1DM for 4–12 months after diagnosis were enrolled [34]. In this study, there was a beneficial effect on C-peptide secretion 12 months after enrollment, accompanied by lower insulin doses. The other study with teplizumab, the AbATE Study, describes a group of "responders" to treatment, defined as those who maintained C-peptide better than the randomized but untreated comparison group at 24 months [35]. Interestingly, there was little or no decline in C-peptide in the responder group, which was about 45% of subjects treated with anti-CD3. This is particularly interesting because in the other anti-CD3 trials, the C-peptide response was transient, with a decline after 6–12 months in parallel to the comparison group. One interpretation could be that the treated subjects were a mixed group, with some being responders and others nonresponders, thus confounding interpretation.

There have been a number of other immune intervention studies conducted in the past 10 years, many by two NIH networks, Type 1 Diabetes TrialNet and the Immune Tolerance Network (ITN). Two of the TrialNet studies showed beneficial results in terms of C-peptide response on a MMTT. One of these used the anti-CD20 monoclonal antibody rituximab, which targets B-lymphocytes [36]. Treatment was weekly for 4 weeks, with the primary outcome measured at 1 year [36] and follow-up at 2 years [37]. Although there was increased C-peptide, the effect appeared to be transient with calculated delay in decline, in comparison to the placebo group, being 8.2 months [37].

One other TrialNet study also showed a beneficial effect using the co-stimulation blocker abatacept [38]. Treatment was monthly for 2 years, with the primary outcome measured at 2 years [38] and follow-up at 3 years, 1 year after cessation of treatment [39]. Although there was a difference in C-peptide response to a MMTT favoring abatacept, there was a decline from the inception, parallel to the placebo group [38]. The difference between the groups suggested that there was a delay of decline of 9.5 months [39].

Another study conducted by TrialNet evaluated mycophenolate mofetil (MMF) (a drug that inhibits purine synthesis used in the proliferation of both B- and T-lymphocytes) with or without initial treatment with the anti-CD25 monclonal antibody daclizumab [40]. This study was halted prior to completion because the Data Safety and Monitoring Board (DSMB) determined that the C-peptide results were no different between each intervention and its control group and that it was futile to expect a difference to emerge.

TrialNet also studied the anti-IL-1β monoclonal antibody canakinumab [41]. Interleukin-1β (IL-1β) is a pro-inflammatory cytokine that recruits effector T-lymphocytes in inflamed tissues, and which also has direct toxic effects on β cells. Unfortunately, the use of canakinumab by itself, given monthly for 1 year, failed to show any difference in MMTT-stimulated C-peptide [41]. Because a study of anakinra, an IL-1β receptor antagonist, was concomitantly completed by the European AIDA Study Group, and also failed to show benefit, both studies were included in a single paper [41]. In contrast, a small pilot study conducted in Buffalo, NY using etanercept, a blocker of tumor necrosis factor (TNF), another pro-inflammatory cytokine, suggested that C-peptide was better in treated than control subjects [42]. It may be that anti-inflammatory agents such as anti-IL-1β or anti-TNF, targeting innate immunity, are best used in combination with agents targeting adaptive immunity, such as anti-CD3, anti-CD20, or co-stimulation blockade.

A recent pilot phase 1 safety study used alpha-1-antitrypsin (AAT) [43]. No safety issues were identified. The study did show that AAT was associated with a down-modulation of IL-1β, which the authors suggested may be proof of benefit for T1DM [43].

ITN conducted a trial using thymoglobulin, a polyclonal anti-lymphocyte preparation that broadly suppresses immune responses [44]. Unfortunately, the results failed to show beneficial effect on C-peptide response.

Another ITN trial evaluated alefacept, a dimeric fusion protein targeting CD2, which is expressed on most T-lymphocytes, but with highest expression on effector memory T-lymphocytes cells and central memory T-lymphocytes, and most prominently on highly pathogenic armed effector T-lymphocytes [45]. Subjects received 12 weekly injections, followed by a 12-week pause, and then another 12 weeks of treatment. Unfortunately during the study, the manufacturer ceased production of the drug and withdrew it from the market, resulting in a smaller than planned sample size. In the treated group, there was no decline in C-peptide from baseline. Yet, the primary outcome, C-peptide during the first 2 hours of a MMTT, failed to meet statistical significance, although a secondary outcome, C-peptide during the full 4 hours of a MMTT, did show benefit versus placebo. Moreover, there was a clear decrease in central memory T-lymphocytes whilst regulatory T-lymphocytes were unchanged [45]. The beneficial effect on C-peptide (using the 4-hour MMTT), together with the pattern of alteration of T-lymphocytes, suggests that targeting central memory T-lymphocytes may be a useful mechanism worthy of further study in T1DM.

Antigen-based therapies are considered highly desirable because they are unlikely to have off-target adverse effects. As noted earlier, oral insulin was used in three studies in recent-onset T1DM without benefit [22–24]. Another diabetes antigen is glutamic acid decarboxylase (GAD). A GAD vaccine, with GAD coupled to the adjuvant aluminum hydroxide (GAD-Alum) has been tested in a number of clinical trials. Although an initial report of a phase 2 study suggested benefit,

at least in those subjects enrolled early after diagnosis [46], this was not confirmed in a TrialNet study [47] nor in a phase 3 study conducted by the manufacturer [48].

Other antigen-based studies, using an insulin B-chain altered peptide ligand [49], or a plasmid-encoded proinsulin [50], also failed to show benefit. Pilot safety studies with a proinsulin peptide showed no harm [51], and additional safety studies are underway (NCT01536431) with both a single peptide, and plans to study a combination of proinsulin peptides. Another pilot study is using alpha methyldopa, which has been shown to prevent antigen presentation by HLA-DQ8 (NCT01883804).

A 24-amino acid peptide derived from heat shock protein 60, called DiaPep277, has been studied in multiple phase 2 trials [52–56] and in a recent phase 3 trial [57,58]. Although there appeared to be promising results from the first phase 2 trial [52,53], results from the other phase 2 trials [54–56] were conflicting. The phase 3 trial gave mixed results, with improved C-peptide versus placebo when stimulated with a GST, but no difference between groups with the MMTT [57,58]. This leaves the results ambiguous.

ITN and TrialNet conducted an open label phase 1 study using a combination of interleukin-2 (IL-2) and rapamycin [59]. The study was halted due to an apparent acute decline in C-peptide in the subjects. It is unclear whether this was due to the high dose of IL-2 used or to adverse effects from the rapamycin. More recently, a safety study has been reported with low-dose IL-2, with no safety issues emerging, including no decline in C-peptide [60]. Further studies with low-dose IL-2 are underway (NCT01862120).

A small pilot study has been done with the combination of low-dose antithymocyte globulin (ATG) and granulocyte colony stimulating factor (GCSF) in patients with diabetes of 4 to 24 months' duration [61]. It demonstrated preservation of β-cell function. As a consequence, a fully powered study with this combination is being initiated in recently diagnosed T1DM.

Another recent combination study evaluated sitagliptin and lansoprazole in patients with recent-onset T1DM [62]. The rationale of this study was that a DPP-4 inhibitor (sitagliptin) would increase serum levels of GLP-1, while a proton pump inhibitor (lansoprazole) would increase serum levels of gastrin. In experimental animals, GLP-1 and gastrin have been shown to increase β-cell mass and function. The hope was that this combination would be beneficial in human T1DM. Unfortunately, there was no difference in β-cell function when comparing the treated subjects and control subjects [62].

A variety of cellular-based approaches have also been attempted. Autologous umbilical cord blood infusion, either alone or followed by docosahexaenoic acid and vitamin D supplementation, has been studied in several small pilot studies [63–66]. This therapeutic approach has been found to be safe. Unfortunately, there has been no beneficial effect on β-cell function.

Autologous *in vitro* manipulated potentially tolerogenic dendritic cells have been studied and have been found to be safe [67]. Some of these dendritic cells were antisense DNA-treated

co-stimulation-impaired immunoregulatory dendritic cells, while some were unmanipulated. However, in spite of the fact that this was a small pilot study, there was the suggestion of upregulation of the frequency of a potentially beneficial B-lymphocyte population [67]. It is interesting that another group studied dendritic cells *in vitro* and found that they had the capability to show tolerance induction to insulin or GAD65, but have not yet treated individuals with these cells [68].

Regulatory T-lymphocytes (T-regs) have also been explored as potential therapy for T1DM [69–71]. One group has studied these in children with T1DM and has shown that repetitive administration of T-regs is safe and may even prolong survival of β cells in T1DM [69,70]. Another group conducted a phase 1 dose-escalation safety study in 14 subjects with T1DM, using autologous polyclonal T-regs that had been expanded from peripheral blood [71]. Infusions were well tolerated with no safety concerns, and infused T-regs were detectable for over 6 months. Subjects exhibited stable C-peptide for as long as 2 years [71]. As a consequence, a full phase 2 study to evaluate safety and efficacy is being initiated.

One therapeutic strategy that has been hailed as having achieved insulin independence is the combination of high-dose immunotherapy, generally with cyclophosphamide and anti-thymocyte globulin, together with nonmyeloablative autologous hematopoietic stem cell therapy (AHSCT) using CD34+ cells isolated from bone marrow [72–77]. The first study, conducted in Brazil, was initially reported in 2007 [72], with updated information reported in 2009 [73,74]. Studies from Poland [75] and China [76] were subsequently reported, and there has been a recent summary of the Polish and Chinese data, including an additional Chinese site [77]. The remarkable finding was that a substantial number of subjects achieved insulin independence, some lasting for as long as 4 years [73,77]. The dilemma is that there were substantial side effects, including a death from Pseudomonas sepsis [77], and that the death rate in other disease states with AHSCT can be as high as 10% [78]. Moreover, the characterization of some of the subjects was such that it was not clear that all had autoimmune T1DM. An important potential issue is whether the interpretation of the mechanism responsible for success is that (a) the effectiveness of AHSCT relies on immunoregulatory properties of CD34+ cells, or that (b) the high-dose immunosuppression is responsible for the beneficial effects with the AHSCT serving to rescue the subject from aplastic anemia and bone marrow failure. If the former, better ways of isolating and using CD34+ cells may be required, while if the latter, safer ways of using immunotherapy would be required.

From the hints of success, it is apparent that some form of combination therapy will be necessary to alter the course of recently diagnosed T1DM [79–81]. It is the author's bias that this will require different modalities, including modulation of the adaptive immune system, suppression of innate immunity, enhancement of protective immunity, all of this possibly in the context of antigen specificity, and some modality that enhances β-cell function and/or enhances β-cell survival [79].

Studies designed to prevent T1DM

Ideally, it would be desirable to prevent T1DM, since earlier therapy may better alter the immune processes, and with earlier therapy there is a greater likelihood that β-cell mass has not been severely compromised. On the other hand, given that clinical disease has not yet emerged, therapies tested must be safe and not likely to have adverse effects. There are two categories of prevention trials—primary prevention and secondary prevention [82]. Primary prevention trials perform genetic screening at birth, and conduct trials in infants with genetic risk of T1DM. Secondary prevention trials involve strategies that either follow a birth cohort with genetic risk until the development of signs of autoimmunity, or screen for autoimmunity amongst relatives (usually first-degree relatives) of individuals with T1DM. Those with genetic risk who are followed from birth for autoimmunity have an extraordinarily high probability of developing T1DM once they develop two or more diabetes autoantibodies [83].

All of the primary prevention trials conducted to date have used dietary interventions. Following epidemiologic studies and meta-analyses that suggested that early introduction of cow's milk may serve as a trigger of T1DM [84,85], a pilot study was initiated to determine if it was feasible to conduct a study in which cow's milk-based formula would not be used [86]. The trial studied babies with high genetic risk, and encouraged breast feeding, but at the time of weaning, randomized infants to receive either a casein hydrolysate formula or a conventional cow's-milk formula (control) whenever breast milk was not available during the first 6–8 months of life. Initial reports were encouraging and eventually even suggested that there might be a reduction of autoimmunity [86]. The feasibility of conducting such trials led to the rather ambitious "Trial to Reduce Incidence of Diabetes in the Genetically at Risk" (TRIGR), which registered over 5000 newborns in 15 countries and randomized 2160 newborns to receive either casein hydrolysate formula or cow's-milk formula [87,88]. Unfortunately, TRIGR did not confirm that there was a reduction in autoimmunity with the casein hydrolysate formula [89].

Other dietary interventions have also been studied. A pilot study, the Finnish Dietary Intervention Trial for the Prevention of Type 1 Diabetes (FINDIA), sought to establish whether an infant formula free of bovine insulin may reduce T1DM autoimmunity [90]. The FINDIA formula resulted in a reduced risk of appearance of one or more antibodies when compared with cow's-milk formula [90].

Observational studies suggested that age of introduction of solid food, particularly gluten-containing foods or cereals, affects the development of autoimmunity in children with genetic risk of T1DM [91,92]. In a pilot study

in antibody-positive children, β-cell function seemed to be improved by deprivation of gluten for 6 months [93]. This led to the BABYDIET study, a randomized controlled trial, which evaluated whether delayed exposure to gluten reduces the risk of diabetes autoimmunity [94]. Unfortunately, delaying gluten exposure until 12 months of age, although safe, did not reduce the risk for diabetes autoimmunity in children at genetic risk of T1DM [94].

Observational studies also suggested that dietary intake of omega-3 fatty acids is associated with reduced risk of islet autoimmunity in children at increased genetic risk for T1DM [95]. The TrialNet Nutritional Intervention to Prevent (NIP) Type 1 Diabetes Pilot Trial assessed the feasibility of nutritional supplementation with the omega-3 fatty acid docosahexaenoic acid (DHA) during the last trimester of pregnancy and the first few years of life [96]. During the relatively brief follow-up, there was no change in autoimmunity although other changes in anti-inflammatory factors suggested that omega-3 fatty acids may have some effects that would need to be further evaluated [97].

The other potential dietary intervention that has received much discussion is vitamin D supplementation. Vitamin D prevents both insulitis and T1DM in mouse models of T1DM [98,99]. Retrospective studies have noted apparent beneficial effects of vitamin D supplementation in early life on subsequent lifetime risk of T1DM [98]. Other studies have not found that to be the case [100], although a meta-analysis of four case-control studies and one cohort study did suggest reduced risk with early vitamin D supplementation [101]. A feasibility study has shown that it is possible to recruit babies from the general population for identification of genetic risk and enrollment to a randomized controlled prevention trial of vitamin D supplementation [102]. Such a full-scale trial is clearly needed to clarify whether or not vitamin D supplementation is truly beneficial.

Finally, another primary prevention strategy under preliminary evaluation is the mucosal presentation of antigen, either orally or nasally. The PrePoint study is evaluating doses of antigen in very high-risk children with genetic markers, to determine whether this may prevent the emergence of islet autoantibodies [103].

It may be argued that one should test vaccines for primary prevention—either vaccines against putative viral or other infectious triggers, or antigen-specific vaccines. To date, no such studies have been initiated.

Several secondary prevention trials have been conducted in subjects who already have diabetes-related autoantibodies. Thus, the outcome measure in these trials is the development of T1DM. Again, like in primary prevention trials, because the research subjects do not have a clinical diagnosis, any intervention to be tested should be safe. Nicotinamide, a water-soluble vitamin (B6) derived from nicotinic acid, was studied in two large multicenter randomized controlled clinical trials in relatives of individuals with T1DM found to be at risk

of the disease because of presence of diabetes autoantibodies [104,105]. These two studies—the German (Deutsch) Nicotinamide Diabetes Intervention Study (DENIS) and European Nicotinamide Diabetes Intervention Trial (ENDIT)—did not prevent or delay development of T1DM [104,105].

Antigen-based strategies have also been studied for secondary prevention of T1DM. The Diabetes Prevention Trial-Type 1 (DPT-1) Study Group conducted two studies evaluating insulin as a potential antigen-based therapy, enrolling relatives of individuals with T1DM screening positive for islet cell antibodies. The two studies used: (i) parenteral (or injected) insulin in individuals with a projected 5-year risk of at least 50% [106], and (ii) oral insulin in individuals with a projected 5-year risk of 25–50% [107]. The parenteral insulin trial tested not only whether insulin as an antigen could modulate immunity, but also whether insulin use might result in "β-cell rest", thus decreasing presentation of antigen to the immune system. However, the rate of development of diabetes was essentially the same in both the treated and control arms of the DPT-1 parenteral insulin trial [106].

In the DPT-1 oral insulin trial, the rate of development of diabetes was essentially the same in both the treated and placebo arms [107]. However, in a post hoc analysis, a subgroup of subjects—those with higher titers of insulin autoantibodies at the time of enrollment—appeared to show a beneficial effect of oral insulin with a projected delay of 4.5 to 5 years in onset of T1DM [107]. Long-term follow-up of the DPT-1 oral insulin cohort showed that even after administration of oral insulin was ceased, effects were maintained [108]. As a consequence of these observations, another oral insulin trial is being conducted by Type 1 Diabetes TrialNet, which is enrolling subjects with characteristics similar to the subgroup that showed delay in T1DM in the DPT-1 trial.

A Belgian trial also evaluated parenteral insulin, and also failed to show a delay in development of T1DM [109].

A trial in Finland, the Type 1 Diabetes Prediction and Prevention Study (DIPP) was conducted in newborns with genetic risk of T1DM (but without a known relative with the disease), followed prospectively for development of diabetes autoantibodies, after which they were treated with nasal insulin or placebo [110]. Unfortunately, again there was no difference in rate of progression to T1DM [110].

Nasal insulin was also studied for safety in the Intranasal Insulin Trial (INIT 1) [111]. No adverse effects were seen. A subsequent study of nasal insulin in patients who already had T1DM, demonstrated that the interferon-γ response of T-lymphocytes to proinsulin was suppressed after nasal insulin [112]. As a consequence, another nasal insulin trial is being conducted by the Australian Diabetes Vaccine Development Centre (DVDC).

In a small pilot trial using low-dose cyclosporine (six subjects compared to nine historical controls) in relatives of T1DM patients with islet cell antibodies and some metabolic

impairment, two of the cyclosporine-treated subjects remained without T1DM for 47 and 57 months [113]. This was not further pursued due to potential cyclosporine toxicity, as discussed earlier.

Several other prevention studies are currently underway. These include a study of GAD vaccination, the DIAPREV-IT (Diabetes Prevention - Immune Tolerance) Study in Southern Sweden (NCT01122446), a TrialNet study with the anti-CD3 monoclonal antibody teplizumab (NCT01030861), and another TrialNet study with the co-stimulation blocker abatacept (NCT01773707).

Conclusions

Hundreds of interventions have been shown to prevent or reverse immune-mediated diabetes in rodent models. Yet, none has been unambiguously successful in human beings, either to prevent T1DM, or to stabilize β-cell function over a protracted time frame. Nonetheless, several human studies have had transient beneficial effects without major safety issues. This raises the prospect that combination therapies may yet prove beneficial [79–81].

Prevention of type 2 diabetes

Thomas Yates and Melanie J. Davies

Diabetes Research Centre, College of Medicine, Biological Sciences and Psychology, University of Leicester, Leicester, UK;
National Institute for Health Research Leicester-Loughborough Diet, Lifestyle, and Physical Activity Biomedical Research Unit, UK

Key points

- Diabetes prevention trials and initiatives have been focused on those with prediabetes, defined by the presence of impaired glucose tolerance (IGT) and/or impaired fasting glucose (IFG).
- If left untreated, up to 70% of those with prediabetes will develop type 2 diabetes (T2DM) over the course of their lifetime.
- Unhealthy lifestyle practices attributable to modern industrialized environments have been shown to account for 80–90% of all cases of T2DM.
- Lifestyle interventions studies have been shown to reduce the risk of developing T2DM by 30–60% in those with prediabetes.
- Some pharmaceutical agents, particularly metformin, have also been shown to be effective in the prevention of T2DM.
- Lifestyle interventions and metformin are likely to be cost-effective in those with prediabetes or even incur a modest cost saving in some subgroups.
- A two-stepped approach, whereby risk scores are used to identify moderate- to high-risk individuals and blood tests are then used to confirm risk (prediabetes) status, is gaining consensus as the cost-effective method of identifying individuals who are suitable for a diabetes prevention program in routine care.
- Diabetes prevention programs focused on lifestyle change have been successfully translated into routine clinical care across diverse healthcare systems internationally.

Prediabetes

Unlike many other chronic diseases, T2DM is not heralded by a discrete physiologic event which defines diagnoses; rather it sits at one end of a continuous glucose control spectrum with normal glucose control at the other. In-between these two boundaries exists a region of abnormal glucose control which is already characterized by concomitant insulin resistance and β-cell dysfunction but does not yet reach the criteria for T2DM [1]. Those diagnosed with T2DM typically spend an extended period in this region of impaired glucose regulation, sometimes for more than a decade, before progressing to T2DM [1]. This affords an identifiable window of opportunity with which to apply primary prevention initiatives aimed at reducing insulin resistance and/or improving β-cell function to slow or reverse progression to T2DM.

Higher than normal glucose levels that are below the threshold for T2DM are defined in various ways depending on the glucose measurement selected and the criteria applied (see Table 38.1). Various terminologies have been used to indicate the presence of at least one glucose measure in this higher than normal range, including prediabetes (the most widely used), nondiabetic hyperglycemia and impaired glucose regulation. Although we recognize the controversy surrounding the term prediabetes, and acknowledge the fact that not all individuals with prediabetes will develop T2DM, where expedient we use this term for brevity and comprehensibility.

Impaired glucose tolerance and impaired fasting glucose

Prediabetes has traditionally been defined by the presence of impaired glucose tolerance (IGT) and/or impaired fasting glucose (IFG). IGT is characterized by elevated postprandial glucose and is identified by means of an oral glucose tolerance test (OGTT) whereby plasma glucose levels are measured 2 hours after a standardized glucose load of 75 g taken in the fasting state. Both the World Health Organization (WHO) and the American Diabetes Association (ADA) recognize 2-hour post challenge glucose (henceforth referred to as 2-h glucose) levels of greater than or equal to 7.8 mmol L^{-1} and less than 11.1 mmol L^{-1} as indicating IGT (see Table 38.1) [2,3].

IFG is characterized by elevated fasting glucose levels. Compared to IGT, there is less international unanimity over the classification of IFG, with ADA recommending values of greater than 5.5 mmol L^{-1} and less than 7.0 mmol L^{-1}, and WHO

Table 38.1 Current WHO and ADA criteria for impaired fasting glucose, impaired glucose tolerance and HbA1c defined high risk states

		Fasting glucose	2-h post challenge glucose	HbA1c
Current WHO criteria [2,17]	Impaired glucose tolerance	<7 mmol L^{-1}	≥7.8 mmol L^{-1} and <11.1 mmol L^{-1}	<6.5% (if measured)
	Impaired fasting glucose	≥6.1 mmol L^{-1} and <7.0 mmol L^{-1}	<7.8 mmol L^{-1}	<6.5% (if measured)
	HbA1c defined high state	No recommendation given	No recommendation given	No recommendation given
Current ADA criteria [3]	Impaired glucose tolerance	<7 mmol L^{-1}	≥7.8 mmol L^{-1} and <11.1 mmol L^{-1}	<6.5%
	Impaired fasting glucose	≥5.6 mmol L^{-1} and <7.0 mmol L^{-1}	<11.1 mmol L^{-1}	<6.5%
	HbA1c defined high state	<7 mmol L^{-1}	<11.1 mmol L^{-1}	≥5.7 % and <6.5%

recommending values of greater than or equal to 6.0 mmol L^{-1} and less than 7.0 mmol L^{-1} (see Table 38.1) [2,3].

IFG and IGT represent distinctive phenotypes with differing pathophysiologies. IFG is predominantly characterized by hepatic insulin resistance, near normal peripheral insulin sensitivity and severely impaired early-phase insulin response following a glucose load [1,4]. IGT is characterized by peripheral insulin resistance, near normal hepatic insulin sensitivity and impaired early-phase and late-phase insulin response following a glucose load [1,4]. Both IGT and IFG are associated with some degree of β-cell dysfunction. Indeed, studies have reported severe impairments in β-cell function in those with IGT and/or IFG with up to 80% decreased function with indirect measures and 50% decreased β-cell volume with autopsy findings [1,5–7].

In most countries around 15% of adults have IGT or IFG based on WHO criteria [2,8]; this figure rises in some minority populations and with age (in some elderly populations up to 1 in 2 individuals are estimated to have prediabetes [9]). Of those with IGT or IFG, an estimated 4–10 % develop T2DM per year, with the highest rates (up to 20%) seen in those with both IGT and IFG [1,2,8]. Evidence from prospective studies suggests that around 25–40% of individuals with prediabetes go on to develop diabetes over a 3–8-year period and, according to an ADA expert panel, up to 70% will eventually develop T2DM over the course of their lifetime [10–13]. Rates closer to 90% have been observed in a long-term (20-year) follow-up of a Chinese population with IGT [14].

The risk of cardiovascular disease and premature mortality is also significantly elevated in individuals with IGT and IFG [2,8]. For example, in the DECODE trial, people with IGT were 50% more likely to die of cardiovascular disease than people with normal blood glucose control [15].Furthermore, as there were four times more people with IGT as with T2DM, there were more premature deaths attributable to IGT than to diabetes [15,16].

HbA1c and prediabetes

Since WHO revised the criteria for the diagnosis of T2DM to include HbA1c [17], there has been continued discussion around the inclusion of HbA1c in the definition of a high-risk prediabetes category analogous to that of IGT or IFG. This is highly clinically relevant as it is potentially burdensome and confusing to define categories on a continuous glucose control spectrum with different measures. Although WHO found insufficient evidence for the use of HbA1c in the definition of prediabetes, recent statements from the American Diabetes Association and an international expert committee recommended that HbA1c can be used to signify a high-risk state at levels of 5.7–6.4 % and 6.0–6.4%, respectively [3,18]. NICE have also recently recommended that HbA1c levels of 6.0–6.4% can be used as an alternative to fasting or 2-h glucose in the identification of prediabetes. Although clinically useful, the effect that this change in classification may have on risk status is unclear; evidence from the UK and elsewhere suggests there is significant discordance in individuals identified with prediabetes through HbA1c or traditional criteria [19,20].

Lifestyle interventions

Unhealthy lifestyles and T2DM are inextricable linked, with the former being the primary causal agent of the latter. Unhealthy lifestyle practices attributable to modern industrialized environments have been shown to account for 80–90% of all cases of T2DM [21]. It has been speculated, through the so-called "thrifty genotype" and "thrifty phenotype" hypotheses [22,23], that phenotypes susceptible to obesity and insulin resistance were bestowed with survival advantages throughout the vast majority of human evolution, which was characterized by the harsh environments associated with hunter-gatherers and early subsistence agriculturists. However, in modern industrialized environments where the traditional cyclical nature of food availability has flat-lined at the highest possible level and the need for purposeful physical activity has been all but engineered out of our daily lives, these previously advantageous phenotypes have become highly deleterious. Given these considerations, lifestyle interventions have traditionally formed the primary therapeutic target in diabetes prevention programs.

Randomized controlled trials have confirmed the primacy of lifestyle in the prevention of T2DM, with lifestyle interventions reducing the risk of progressing to T2DM by 30–60% in those with prediabetes [24,25]. For example, the Finnish Diabetes Prevention Study (DPS) found that the risk of T2DM was reduced by 58% in those given lifestyle counseling compared to control conditions over a 3-year period [26]. Similar findings were seen in the USA in the Diabetes Prevention Study (DPP) [27]. These results have also been replicated across diverse countries and cultures including India [28], Japan [29], and China [30]. Table 38.2 details the main characteristics of these trials.

Importantly, the benefits of successful lifestyle change programs have also been shown to be lasting over the longer term. DPS, DPP, and the China Da Qing prevention study have all found sustained reductions in the incidence of T2DM relative to the control group over 7–20 years of follow-up [14,31,32]. These results were achieved even though the active lifestyle intervention discontinued after the initial study period. Therefore it would appear that once individuals are enabled to successfully change and self-regulate their health behavior, benefits can be accrued long after behavioral counseling has ceased.

Lifestyle interventions aimed at the prevention of T2DM in those with prediabetes have all been based on the promotion of moderate to vigorous intensity physical activity, a healthy diet, and weight loss for overweight or obese individuals or weight maintenance for normal-weight individuals (see Table 38.2). Each of these interventional components has independent effects on the risk of T2DM.

Obesity

Weight loss, of between 5 to 10% of initial body weight and maintenance, was a core component of all successful diabetes prevention programs. Although obesity and T2DM are symbiotically linked, the pathophysiology of how adiposity causes the development of T2DM is not fully understood; however, several mechanisms have been postulated. Adipose tissue, especially the tissue surrounding internal organs, is known to be an active endocrine organ that secretes a variety of pro-inflammatory adipokines, which act at both the local and systemic level [33]. Increasing adipose tissue mass leads to adverse changes in the profile of secreted adipokines as well as increased turnover of free fatty acids, which lead to increased insulin resistance. Interestingly, beneficial changes in glucose metabolism have been shown to appear soon after the initiation of an energy-restricted diet, even before any significant reduction in body fat is seen, which suggests that there are several different mechanisms in play simultaneously [34].

Chapter 6 provides a detailed description of the role of adiposity in glucose regulation.

Two of the most effective diabetes prevention studies (DPP and DPS) achieved an average of 5–7% weight loss among participants in the lifestyle intervention while post-hoc analysis from DPP identified weight loss as the main driver of changes in diabetes incidence, with each kilogram of weight loss being associated with a relative reduction of 16% in the risk of progression to T2DM [35]. Others have reported that weight reduction seems to be beneficial regardless of the mechanism of weight loss (e.g. diet or physical activity or both) [36], a hypothesis that is supported by studies showing significant reduction in the risk of T2DM following weight loss initiated through pharmaceutical intervention [37].

Physical activity

Whilst there is little doubt that weight loss is generally important to the prevention of T2DM, it is also true that changing other facets of lifestyle behavior can have profound effects on glucose regulation even in the absence of weight loss. Therefore, weight loss is not a prerequisite for improved glucose regulation. For example, the lifestyle intervention within the Indian Diabetes Prevention Programme did not result in weight loss despite a significant reduction in the relative risk of T2DM of around 30% compared to the control group [28]. This is an important message considering that the majority of individuals find weight reduction difficult to sustain in the long run, meaning other factors are needed if long-term reductions in the risk of T2DM are to be achieved. One of the most potent and universally applicable adiposity-independent therapeutic agents in the prevention of T2DM is physical activity.

Undertaking insufficient physical activity is associated with over 20 diseases and conditions and is estimated by the World Health Organization to be the fourth leading cause of premature mortality globally [38], ahead of both obesity and dietary factors. Somewhat rarely for lifestyle factors, evidence for a causal link between physical activity and the prevention of T2DM is supported by the full spectrum of evidence needed to infer causality, from observational research [39,40], to experimental mechanistic exploration [41–43] to randomized controlled trials and meta-analyses [24,47].

Observational research has confirmed that physical activity is a strong determinant of health in those with prediabetes. For example, in a large international cohort with prediabetes every 2000 steps per day change in walking activity over a 12-month period, as measured by a pedometer, was associated with an 8% difference in the risk of cardiovascular disease [39]. Others have shown that undertaking 150 minutes of leisure time walking activity per week was associated with a 60% reduction in the relative risk of diabetes [40].

Mechanistic studies have identified multiple pathways linking physical activity to insulin-stimulated glucose uptake [41–43]. Interestingly, muscular contractions are also known to induce glucose update through insulin independent pathways, which are likely to involve the upregulation of AMP-activated kinase [42]. Furthermore, muscle is an active endocrine organ and releases a plethora of myokines which are regulated by muscle fiber activation. For example, IL-6 is released from vigorously contracting muscle in quantities up to 100 times greater than resting values; this is turn has profound anti-inflammatory

Table 38.2 Characteristics of lifestyle diabetes prevention programs

Study	Country/study name	Sample size	Inclusion criteria	Interventions	Lifestyle intervention targets	Intervention duration	Risk reduction at end of intervention period (% reduction compared to controls)
Pan et al., 1997 [30]	China /The Da Qing IGT and Diabetes Study	530 (283/247)	IGT, Age ≥25	**1** Control **2** Diet **3** Exercise **4** Diet and exercise	**Diet group:** Weight maintenance for those with a BMI <25 kg m⁻² through a healthy isocalorific diet. Weight reduction for those with a BMI ≥25 kg m⁻² through reduced energy intake **Exercise group:** Participants were encouraged to increase the amount of their physical activity by at least one unit per day (such as slow walking for 30 min, or fast walking for 20 min) and by two units per day if possible **Diet-plus-exercise group:** Combination of above	6	Diet: 31 Exercise: 46 Exercise and diet: 42

effects which can act to augment improvements in insulin action [44]. Physical activity acts to favorably alter the distribution and composition of adiposity within the body. For example, increased physical activity is associated with reduced levels of hepatic fat, even without whole body weight loss, and recent evidence points to the role of physical activity in the promotion of brown adipose tissue [45,46].

Randomized controlled trials and meta-analyses have demonstrated that physical activity interventions result in improved glucose regulation and a reduced risk of T2DM in those with prediabetes [24,47]. For example, an exercise intervention in those with IGT was shown to reduce 2-hour post challenge glucose values by 1.3 mmol L^{-1} over 12 months and reduce the risk of T2DM by a 60% over 24 months [47,48]. This is consistent with other studies and the results of a meta-analysis which demonstrated that physical activity interventions result in around a 50% reduction in the relative risk of type diabetes and are as effective as other multifactorial interventions that also promoted a healthy diet and weight loss [24].

As mentioned earlier, many of the benefits of increased physical activity are independent of overall body weight and adiposity. Observational research and interventions have consistently demonstrated substantial improvements in glucose regulation and reduced cardiovascular disease risk with higher levels of physical activity despite no significant change to body weight or waist circumference [39,40,42,47,49]. Therefore it is clear that the promotion of physical activity significantly improves glucose regulation, even in the absence of weight loss.

Successful diabetes prevention programs have typically promoted at least 150 minutes of moderate intensity physical activity per week, which is consistent with current international and national physical activity recommendations for health [50,51]. However, post-hoc analysis of diabetes prevention studies and epidemiologic evidence has consistently demonstrated a dose–response relationship between the amount of physical activity undertaken and the risk of T2DM, and recommendations for health now specifically state that greater benefits will accrue through achieving higher volumes of physical activity [50,51].

Diet

In addition to weight loss, diabetes prevention programs have targeted a reduction in total and saturated fat, with increased fiber intake. For example, DPS had three dairy goals: (1) less than 30% of energy intake derived from fat, (2) less than 10% of energy intake derived from saturated fat, and (3) at least 15 g of fiber per 1000 kcal [26]. Post-hoc analysis subsequently revealed that each one of these factors was related to the risk of T2DM, independent of body weight; compared to the lowest quartile, the risk of T2DM was approximately doubled in the highest quartile of total and saturated fat intake, and reduced by 60% in the highest quartile of fiber intake [52]. Other observational research studies and experimental interventions have consistently demonstrated the importance of these factors, particularly increased fiber and reduced saturated fat, in helping promote improved insulin sensitivity and a reduced risk of T2DM [53]. Plausible mechanisms linking these factors to insulin action have been proposed, including reduced ectopic fat, reduced low-grade inflammation, changes in cell membrane phospholipids, and enhanced intestinal peptide secretion [54,55].

As well as specific dietary factors, observational studies have suggested that overall dietary patterns are also an important consideration. For example, those consuming a "Westernized diet" (intake of refined grains, red and processed meat, sugar-sweetened beverages, high-fat dairy) have substantially higher risk (RR = 1.59) compared to those who do not, independently of body weight [56]. At the opposite end of the spectrum, those consuming a prudent diet (intake of whole-grain cereal, vegetables, legumes, low-fat dairy products, nuts, seeds, fish, and poultry), have a lower risk of T2DM [56]. A recent intervention further confirmed the importance of dietary patterns, where those assigned to a Mediterranean diet, characterized by high intake of vegetables, fruit, legumes, extra virgin olive oil, nuts, fish, whole grains, and red wine, decreased their risk of T2DM by 50%, without reductions to body weight [57].

Pharmaceutical intervention

An expanding range of pharmaceutical agents targeting β-cell function or insulin sensitivity have been tested in the prevention of T2DM over the last two decades; these can be broadly grouped as metformin, thiazolidinediones, α-glucosidase inhibitors, meglitides, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and weight loss therapies. The primary studies investigating each of these classes of agents in the prevention of T2DM are discussed in the following sections and the main characteristics are displayed in Table 38.3. In addition, we highlight some new classes of drugs that have potential in the prevention of diabetes.

Metformin

Metformin is the most widely researched and best understood agent in the prevention of T2DM. It is classed as a biguanide and acts through suppressing hepatic glucose production and inhibiting free fatty acid production and oxidation, therefore reducing insulin resistance and promoting peripheral glucose uptake [58]. A recent meta-analysis demonstrated an average reduction in the risk of T2DM of 40% with metformin [59]. In DPP, metformin was associated with a 31% reduction in the incidence of T2DM at 3 years with an NNT of 13.9 [11]. Metformin was found to be most effective in younger adults and those with a higher BMI [11]. Metformin is known to have some gastrointestinal side effects (diarrhea, flatulence, nausea, and vomiting), however the therapy is generally well tolerated and these side effects are typically not treatment limiting. For example in DPP, metformin was associated with increased gastrointestinal symptoms (77.8 compared with 30.7 events/100 person-years with placebo), but adherence to metformin treatment was only slightly affected (77% with placebo vs. 72% with metformin took at least 80% of the prescribed dose) [11].

Table 38.3 Characteristics of diabetes prevention programs evaluating pharmaceutical agents

Study name	Country	Agent(s) tested	Study design	Sample size (male/female)	Inclusion criteria	Intervention duration	Risk reduction at end of intervention (% reduction compared to placebo)	Most common side effect
Diabetes Prevention Program [27]	USA	Metformin	RCT (placebo-controlled)	3234 (1043/2191)	IGT , BMI $\geq$24 kg m^{-2} ($\geq$22 kg m^{-2} if Asian), fasting plasma glucose $\geq$5.3 mmol L^{-1}	2.8	31	Gastrointestinal symptoms
STOP-NIDDM [12]	International	Acarbose	RCT (placebo-controlled)	1368 (673/695)	IGT, fasting between 5.6 and 7.8 mmol L^{-1})	3.3	25	Gastrointestinal symptoms
DREAM [13,75]	International	Rosiglitazone Ramipril	2 × 2 factorial (placebo-controlled)	5269 (2149/3120)	IGT and/or IGT without known CVD or renal impairment	3	**Rosiglitazone:** 69 **Ramipril:** no effect	**Rosiglitazone:** edema, congestive heart failure, weight gain **Rampiril:** cough
ACT-NOW [65]	USA	Pioglitazone	RCT (placebo-controlled)	602 (58% female)	IGT, fasting between 5.3 and 7.8 mmol L^{-1}), and at least one other risk factor	2.4	72	Edema, weight gain
NAVIGATOR [71,76]	International	Nateglinide Valsartan	2 × 2 factorial (placebo-controlled)	9306 (4595/4711)	IGT with established cardiovascular disease or cardiovascular risk factors	5	**Nateglinide:** no effect **Valsartan:** 14	**Nateglinide:** hypoglycemia **Valsartan:** hypotension-related effects
XENDOS [37]	Sweden	Orlistat	RCT (placebo-controlled)	3305 (1810/1495)	Nondiabetic obese adults	4	37	Gastrointestinal symptoms

Lactic acidosis, the most severe side effect of biguanides in general, is also rare with metformin. Nonetheless, as with the treatment of T2DM, clinical caution is needed for patients with limited renal function or heart failure.

As well as the primary effect on glucose uptake, several relevant pleiotropic effects have been postulated for metformin, specifically the prevention of cardiovascular disease and cancer [60,61]. However, whilst each of these potential benefits has supporting observational and mechanistic evidence, data from placebo-controlled randomized trials is lacking or inconclusive.

Given its proven efficacy, the limited side effects and possible additional cardioprotective action, metformin is increasingly considered a suitable alternative or adjunct to lifestyle intervention strategies in the prevention of T2DM. For example, ADA recommends that metformin should be considered for those with both IGT and IFG and one additional factor [10]. NICE has also recently recommended that metformin should be considered when lifestyle intervention has been tried and found to be ineffective [62].

Thiazolidinediones

Thiazolidinediones (TZDs) are hepatic and peripheral insulin sensitizers which stimulate peroxisome proliferator-activated receptor-γ (PPAR-γ) activity including the promotion of adipogenesis and fatty acid uptake in peripheral but not visceral fat [63]. TZDs favorably alter adipokine profiles, particular increased adiponectin, which is associated with increased insulin sensitivity. In addition TZDs are also associated with β-cell preservation [64].

Two types of TZDs, rosiglitazone and pioglitazone, have been rigorously assessed and found to reduce the risk of T2DM by 60–70% over a 2.6- to 3-year period in those with prediabetes [13,65]. For example the DREAM trial, which included over 5000 participants, demonstrated a 60% reduction in the relative risk of T2DM in those randomized to receive rosiglitazone with a NNT of 7 [13]. In addition, rosiglitazone significantly increased regression to normoglycemia by 70–80% compared to placebo.

However, the impressive efficacy of TZDs in the prevention of T2DM is counterbalanced by serious side effects, which makes their use clinically inappropriate for this group. Trials have shown significant weight gain (2.6–7 kg) compared to placebo, which is unsurprising given TZDs directly promote adipogenesis. More worrying, TZDs are also associated with an increase risk of cardiovascular disease, including increased myocardial infarction and heart failure, and other adverse health effects [66,67].

Alpha-glucosidase inhibitors

α-Glucosidase inhibitors primarily act to delay carbohydrate absorption, therefore blunting the postprandial glucose response and reducing the toxic effect of elevated glucose concentrations on pancreatic β cells; in addition, α-glucosidase inhibitors directly improve insulin sensitivity in individuals with IGT [68]. In STOP-NIDDM, an international double-blind placebo-controlled trial involving 1368 randomized participants with prediabetes, acarbose was found to reduce the risk of T2DM by 25% over 3.3 years [12]. Other studies in those with prediabetes have been shown to have similar effects [69]. Acarbose has also been postulated to reduce the risk of cardiovascular disease which is supported by some experimental research and a meta-analysis of studies predominately undertaken in those with T2DM [70]. However, no published study has yet been specifically designed to assess this outcome.

Meglitinides

Nateglinide is a D-phenylalanine analogue, which acts directly on the β cells to stimulate a rapid short-duration secretion of insulin, thereby controlling postprandial hyperglycemia. NAVIGATOR, a multinational randomized 2×2 factual placebo-controlled trial involving over 9000 participants, was designed to test the efficacy of nateglinide and valsartan at lowering incidence of T2DM and cardiovascular events in high-risk participants with prediabetes [71]. At 5 years, no significant difference was seen between placebo and nateglinide in these primary outcomes.

Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers

In addition to cardiovascular benefits in those with T2DM, renin-angiotensin system (RAS) inhibitors have consistently been related to a reduced risk of T2DM in post-hoc analysis of antihypertensive trials [72–74]; however, these trials were limited by possible adverse effects to glucose control from the active comparators used. Only valsartan and rampril have been specifically evaluated in the prevention of T2DM. In the DREAM trial, rampril was not related to a reduced incidence of T2DM or CVD compared to placebo [75]. In the Navigator trial, valartan was associated with a small (14%) reduced risk of T2DM compared to placebo; however, no effect was seen on cardiovascular outcomes [76].

Insulin analogues

Given that β-cell dysfunction is one of the underlying causes of T2DM and is already present in prediabetes, early treatment with insulin analogue therapy may be effective at reducing the progression to T2DM in high-risk individuals. This hypothesis was recently assessed in the ORIGIN study; an international double-blind study with a 2×2 factorial design comparing insulin glargine and N-3 fatty acid supplementation against placebo [77]. In total, 12,537 patients with cardiovascular disease or at high risk for cardiovascular event who had prediabetes or diabetes were randomly assigned to receive insulin glargine, N-3 fatty acids supplementation or placebo. Among the 1456 patients with prediabetes at baseline, insulin glargine was associated with a 20–30% reduction in the relative risk of progressing to T2DM, depending on the time point assessed [77]. However, rates of weight gain and hypoglycemia were greater in the insulin glargine group and treatment was not

associated with a reduction in cardiovascular events after 6 years in the study cohort overall [77].

Weight loss therapies

Given the primacy of obesity in the development of T2DM, weight loss is an obvious therapeutic target for prevention. However, weight-reducing agents have only been studied in small numbers and only one, orlistat (an intestinal lipase inhibitor), has been specifically evaluated in the prevention of T2DM. In the XENDOS trial, 3304 nondiabetic obese subjects received lifestyle modification and were randomized to either orlistat or placebo for 4 years [37]. There was a weight loss of 6.9 kg in the orlistat group (compared with 4.1 kg in the placebo group) after 4 years that was associated with a 37% reduction in the relative risk of T2DM; this figure rose to 45% in those with IGT at baseline. However, low rate of completion (52% in the orlistat group) limits the conclusions that can be drawn from this study suggests poor acceptability among participants.

Other agents

There are several newer classes of therapies developed for use in the treatment of T2DM that target glucose control and weight loss, and show strong potential in the prevention of T2DM.

Glucagon like peptide-1 (GLP-1) analogues and dipeptidyl peptidase-4 (DPP-4) inhibitors

GLP-1 is a potent insulin secretagogue which is released by the L cells of the large intestine in response to food ingestion. GLP-1 analogues that mimic the action of GLP-1, but which are resistant to DPP-4 degradation, such as liraglutide and exenatide, have proven to be effective in the treatment of T2DM [78]. Similarly, therapies that inhibit the action of DPP-4, and hence slow the degradation of endogenous GLP-1, have also proven effective [78]. These therapies are attractive in the prevention of T2DM because they are glucose dependent, meaning their effect on insulin secretion is proportionate to the amount of circulating glucose, thus reducing the risk of hypoglycemia. In addition, GLP-1 analogues result in significant and sustained weight loss, with the greatest effects seen in those with the highest levels of obesity [79]. For example, just 20 weeks of liraglutide therapy has been shown to be more effective than orlistat in the treatment of obesity and resulted in a reduced prevalence of prediabetes by 84–96% depending on the dosage used [80]. Ongoing studies are testing the efficacy of GLP-1 therapy in the prevention of T2DM in high-risk groups.

Sodium glucose co-transporter 2 (SGLT2) inhibitors

SGLT2 inhibitors are a new class of therapy that work independently of insulin by preventing glucose reabsorption from glomerular filtration, resulting in glycosuria and a net loss of energy. SGLT2 inhibitors have been shown to improve glycemic control and induce weight loss of up to 5 kg resulting from an average energy loss of around 22–300 kcal per day [81]. However, studies have yet to be undertaken in the prevention of T2DM.

Lifestyle versus pharmacotherapy

Although national organizations and regulatory authorities are increasingly recommending the use of metformin, with the addition of other agents likely in the future, there remains some controversy around the use of pharmaceutical intervention as an adjunct, or in addition, to lifestyle intervention. First, few studies have assessed whether an additive benefit is gained by using lifestyle and pharmaceutical intervention in combination. The only study to have looked directly at outcome rates, the Indian Diabetes Prevention Programme, found that there was no additional benefit of combining metformin with lifestyle modification over and above lifestyle modification on its own in those with IGT [28]. Second, some drugs may actually act to attenuate the beneficial effects of lifestyle intervention. For example, there is mounting evidence that metformin may blunt the insulin sensitizing effects of exercise training in those with prediabetes or diabetes [82,83]. Third, lifestyle change is associated with multiple and wide-ranging health benefits that target the known comorbidities that accompany T2DM as well as general health and well-being. For example, physical activity is associated with a reduced risk of all-cause mortality, a reduced risk of cardiovascular morbidity and mortality, increased physical functioning and a reduced risk of depression [84]. Furthermore, an unhealthy lifestyle, not deficiency in metformin or other pharmaceutical agents, is the primary causal factor for T2DM. Therefore, lifestyle modification programs should be the focus of diabetes prevention initiatives. Whilst logistical and feasibility issues remain in implementing lifestyle programs in a primary healthcare or community settings (see following sections), it is the responsibility of funding bodies and research organizations to address this need. However, we acknowledge that pharmacotherapy may have a role to play when lifestyle modification programs have been tried and found to fail. This is consistent with new recommendations from NICE which advocate the use of metformin where high-risk individuals are unable to take part in a lifestyle intervention program or where lifestyle intervention has been ineffective at stabilizing or lowering glucose levels [62].

Cost-effectiveness

Cost-effectiveness modeling studies using different methods and assumptions have consistently found, based on results from the major prevention trials, that lifestyle intervention and metformin are likely to be cost-effective or incur a modest cost saving [85]. Only one study, out of over a dozen conducted to date, has found that lifestyle or metformin interventions may be near or outside the range considered cost-effective by most healthcare organizations (at $25,400 and $143,000 per QALY gained, respectively) [86]. Importantly, when considering the whole process from screening to treatment, Gillies et al. estimated that screening for T2DM and IGT and tailored treatment to each group were more cost-effective than screening for T2DM

alone in the UK [87]; in addition the use of lifestyle intervention was more cost-effective than pharmaceutical therapy (£6242 vs. £7023 per QALY gained). NICE recently supported this work by suggesting that screening for T2DM and high-risk individuals would be cost-effective at £10,000 per QALY gained or less, and may be cost-saving for some groups [62].

Translation of diabetes prevention into routine primary care

National healthcare policies and funding structures have started to provide significant investment and commitment to the prevention of T2DM. This has necessitated a parallel shift in the focus of diabetes prevention research, to include the translation of effective prevention strategies into routine clinical practice [88]. This work has highlighted several key considerations around two specific areas: (1) suitable strategies to identify high-risk individuals, and (2) the incorporation of lifestyle interventions into routine clinical services.

Identifying those at high risk

Diabetes prevention initiatives have primarily focused on identifying and treating high-risk individuals with IGT, which is diagnosed through the oral glucose tolerance test (OGTT). However, there are important practical limitations regarding the utility and clinical value of carrying out OGTTs to identify those with a high risk of T2DM in routine care. Recently, this issue has been further complicated by the change in criteria for the diagnosis of T2DM to include HbA1c (at a threshold of 6.5% or higher) [17]; many healthcare organizations have, or are expected to, adopt HbA1c as the primary diagnostic tool for T2DM. It is therefore unlikely that the more invasive and burdensome OGTT would be acceptable in the identification of prediabetes. In addition, there are clinical concerns around patient compliance to fasting procedures and the test-retest reliability of 2-hour glucose values. Therefore, advocating the routine use of OGTTs as a screening tool in primary care is unlikely to be appropriate in most healthcare settings [54,89].

The utility of IGT and IFG have also been questioned in the prevention of T2DM [89]. There is high variation in the risk of developing both T2DM and cardiovascular disease across categories of prediabetes; importantly there is also a gradation of risk in those classified with normal glycemia. For instance, data from DPS found that the risk of T2DM in those with IGT more than doubled with the presence of other readily identifiable risk factors [90]. It is also known that the risk of cardiovascular disease increases linearly with increasing levels of 2-h glucose and fasting glucose [91] and there does not appear to be a distinct threshold that justifies the use of distinct risk categories. Given these concerns, there has been much focus on developing pragmatic systematic approaches to the identification of individuals with an elevated risk of T2DM for referral into diabetes prevention

initiatives. These have primarily evolved around the use of risk score technology.

Risk scores

Risk scores rely on utilizing clinically captured or self-assessed determinants or correlates of T2DM to calculate individual risk without the need for additional blood tests. Several risk assessment tools have been developed in the identification of those with a high risk of T2DM, the most widely validated and used of which is FINDRISC. FINDRISC was developed in Finland and uses weighted scores from eight risk characteristics to calculate an overall risk score [92]. FINDRISC has been shown to have good sensitivity (~0.8) and specificity (~0.8) at predicting the 10-year absolute risk of T2DM in a white European population. Similar results were seen for a risk score developed in Germany [93]. Further risk scores have been adapted to, and validated cross-sectionally in, diverse populations. For example, the Leicester Diabetes Risk Score, the Danish Diabetes Risk Score, and the Indian Diabetes Risk Score have all been associated with a sensitivity of 70–80% and a specificity of 55–75% [94–96] of detecting prediabetes and/or T2DM. These risk scores have typically been designed to be used by individuals to self-assess their own risk of T2DM; for example the Leicester Diabetes Risk Score was developed with input from patient groups in order to maximize uptake and comprehensibility [94]. However, recent innovations have included the development and validation of risk scores specially designed for use on data which is routinely available to and stored by general practitioners [97–99]. This allows practitioners to interrogate their patient databases to identify individuals with a high risk of T2DM. For example, the Leicester practice risk score, which uses six variables (sex, age, ethnicity, BMI, family history of T2DM, and antihypertensive medication) that are commonly coded within primary care databases in the UK, has been developed into an automated platform that automatically ranks all individuals registered within a given healthcare organization for their diabetes risk [98].

Two-stepped approach

Given their ease of use and noninvasive methodology, diabetes risk scores are now routinely used within many healthcare organizations. However, an emerging consensus (based on screening approaches used in clinical practice in the USA, Germany, Australia, Finland, the UK, and other countries) favors a targeted, staged approach whereby risk scores are used to identify moderate- to high-risk individuals and blood tests are then used to confirm risk status [54]. This approach has been shown to be the most cost-effective method of identifying those with a high risk of T2DM [100]. Following the most comprehensive review and in-depth analysis of the effectiveness and cost-effectiveness of different screening approaches to date, NICE developed a systematic two-stepped algorithm involving risk score technology to identify individuals ranking above the 50th percentile of risk; individuals meeting this criteria are then recommended to receive either a fasting or HbA1c blood

test to confirm their risk status before preventative action is undertaken [62].

Despite the potential clinical utility of diabetes risk score technology and simple blood tests in the identification of high-risk populations for referral into diabetes prevention initiatives, it is important to recognize that such approaches are not yet supported by gold-standard evidence. Previous diabetes prevention programs have involved specific populations identified on the basis of an OGTT. Therefore, there is a lack of data from randomized controlled trials investigating whether intervening in high-risk individuals, as identified through a risk score or a staged approach, is as effective at reducing the risk of developing T2DM. This is an important limitation because at-risk individuals identified through a risk score only or staged approaches may contain a relatively small proportion of individuals with IGT, the traditional target of intervention studies. Because IGT is specifically characterized by peripheral insulin resistance, it is likely to be more responsive to targeted intervention, particularly lifestyle, than other defined high-risk states.

Implementing prevention programs

As we have seen earlier, there is unequivocal evidence that lifestyle interventions work in the prevention of T2DM and are likely to be highly cost-effective. However, there is huge gap between evidence-based effectiveness and what is feasible in a real-world healthcare setting. Large clinical trials are conducted in ideal settings and apply significant and concentrated resources in pursuit of their goals [88]. For example, the lifestyle intervention within DPP involved 16 lengthy one-to-one counseling sessions, followed by monthly contact with in-person one-to-one contact at least once every 2 months and additional group-based sessions four times annually [11]. This degree of intervention intensity is far greater than even that offered to those with serious diseases in routine clinical care. Therefore, as others have noted, emphasis needs to be placed on examining the minimum level of intensity needed to produce meaningful clinical effects [101]. Beyond that, there are considerations around how new interventions become imbedded within usual care pathways and gain universal access. Prof. Ann Albright, Director for Division of Diabetes Translation within the Centers for Disease Control and Prevention (CDC), identified six distinct steps from basic science to national distribution, termed the continuum of translation, that have to be completed in order to achieve the universal implementation of diabetes prevention [102]. More recently, Schwarz and colleagues identified six key areas of focus to ensure sustainability when implementing diabetes prevention programs into practice, including: (1) intervention cost, (2) training and expertise of intervention providers, (3) uptake to both screening and intervention, (4) ensuring sustainability of funding and support within healthcare and political arenas, (5) developing quality management across intervention providers, and (6) using and improving technology to support behavior change of both patients and healthcare professionals [54].

Finland and the USA have been at the forefront of integrating diabetes prevention programs into usual healthcare systems. Finland adopted a regional systematic whole system approach across all sectors of the healthcare community and included population-based strategies, high-risk strategies, and early diagnosis and management strategies [103]. The high-risk strategy is based on using risk scores to screen the population in primary care, pharmacy, and community settings and then offering tailored lifestyle interventions based on the goals of DPS, generally delivered through 4–8 group-based sessions, to those found at high risk. In the USA, the Centers for Disease Control and Prevention (CDC) have received substantial funding and political support to implement a community-based diabetes prevention program run through YMCA and community facilities [104]. This program, consisting of 16 1-hour group-based sessions delivered by trained quality assured lifestyle coaches, has gained public and private support and has been integrated into the healthcare package offered by some health-insurance companies. Numerous smaller scale diabetes prevention programs, based on the goals of DPP, have also been developed and evaluated in the USA [105]. Internationally, European-wide diabetes prevention guidance and tools for healthcare professionals have also been developed and published [106].

Other groups have also recently begun to design and evaluate interventions that are specifically tailored to the structure and resources available to their national healthcare services. In the United Kingdom, a less resource-intensive, 3-hour group-based structured education program, based on models and systems used in the management T2DM, has proven highly effective at promoting health behavior change and improving glucose regulation in those with prediabetes over 1 year with results sustained at 2 years [47,48]. This theory-driven program, titled "Walking Away from Type 2 Diabetes," has been fully developed into a nationally available diabetes prevention program with accredited educator training and quality assurance professional pathways [107]. Other similar approaches have been developed in Germany and Australia [88].

Intervention designed to translate the findings from diabetes prevention trials into practice, although developed concurrently across diverse healthcare settings and populations, have commonality across several key areas: they have concentrated on lifestyle, tended to utilize group-based education and counseling approaches, and have been delivered across a range of primary care and community venues by personnel largely outside of traditional clinical practice (i.e., other than general practitioners or nurses) [89,105,108]. Several recent systemic reviews and meta-analyses have found that where evaluated, these interventions continue to demonstrate positive outcomes on body weight and other markers of health behavior [105,108]. For example, the average weight loss in interventions modeled on DPP was 4 kg at 12 months compared to 6.5 kg seen in the original DPP trial. Therefore, whilst interventions aimed at translating diabetes prevention programs into routine care have, by necessity, had to use less

resource-intensive methodology, they have continued to show sustained benefits.

High risk versus population

The focus of this chapter and the main discourse on diabetes prevention internationally has been on developing and evaluating upstream strategies designed for high-risk populations. By their very nature such approaches only treat the end-products of a deleterious system, they do not seek to identify and address the underlying fault. This was recognized by Geoffrey Rose 30 years ago with his widely publicized "prevention paradox," which states that strategies designed to shift the population distribution of known risk factors are inherently the only way of effectively tackling a mass disease [109]. Some causal determinants of T2DM, such as obesity and physical inactivity, are now so common that only population-based interventions will begin to fully tackle these issues. This concept was highlighted in a recent study which estimated that a 1% decrease in BMI across the whole population (roughly equal to weight loss of 1 kg per person) would avoid 179,000–202,000 incident cases of diabetes, 122,000 cardiovascular diseases, and 32,000–33,000 incident cases of cancer over the next 20 years in the UK [110]. Therefore, along with high-risk and disease management strategies that remain important for widely prevalent conditions, mass action, similar to that employed to target smoking, is needed involving government policy, legislative and taxation support, and industry compliance to alter the default patterns of behavior associated with our everyday environments. Although infrequently attempted or evaluated, such downstream initiatives have been found to be effective at reducing cardiovascular risk factors within the population [111]. However, the "paradox" remains that interventions applied to the population can lead to little individual benefit and can even cause some individual dissatisfaction. For example, a healthy individual may wonder why their "right" to eat what they like is being infringed by a differential taxation system that targets certain food types. For this reason, employing such population-wide initiatives carries greater controversy and political risk and is therefore generally less likely to be enacted to the extent needed. However, to do nothing, or to continually be at the mercy of shifting and ineffectual political priorities, will expose millions of individuals to obesity and its consequences for generations to come.

Conclusion

It is clear that the prevention of T2DM is a public health priority. There is unequivocal evidence that lifestyle interventions, based on the promotion of physical activity, diet and weight loss, and some pharmaceutical interventions, are highly effective and cost-effective in the prevention of T2DM. Effective translation of lifestyle interventions into routine healthcare settings has remained a challenge; however, recent advances have demonstrated considerable success in effectively tailoring and delivering pragmatic diabetes prevention programs in "real world" routine clinical and community settings. These advances have been matched by government policies that are beginning to prioritize the prevention of chronic disease. Therefore, we stand at a unique crossroads; all the elements required to radically address and reverse this highly prevalent chronic disease have been developed. Whether or not these elements can be adequately combined to realize this potential will depend on whether the academic community, medical profession, healthcare organizations, local authorities, national governments, and industry can join forces and act together with a common purpose.

Prevention of diabetic microvascular complications

Alice P.S. Kong and Juliana C.N. Chan

Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong SAR, China;
Li Ka Shing Institute of Health Sciences, The Chinese University of Hong Kong, Hong Kong SAR, China

Key points

- Good control of blood glucose, blood pressure, and lipids are all vital in preventing diabetic microvascular complications. Structured care and an all-encompassing approach in intensified management of multiple risk factors are recommended.

- Renin-angiotensin-aldosterone system (RAAS) blockade with either angiotensin converting enzyme inhibitor (ACEI) or angiotensin II-receptor blocker (ARB) confers additional protective effects in primary and secondary prevention of diabetic nephropathy, a beneficial effect independent of blood pressure lowering.

- The role of other approaches to achieve complete blockade of RAAS including dual blockade with ACEI and ARB, aldosterone receptor antagonists or direct renin inhibitor need to be explored with more definitive clinical trial evidence.

- Therapies targeting multiple metabolic pathways in preventing the development of diabetes-related microvascular complications including diabetic neuropathy have been attempted and may shed light on future treatment.

- Antivascular endothelial growth factors (VEGF) inhibitors and anti-inflammatory agents such as corticosteroids may play a role in preventing the progression of diabetic retinopathy.

Introduction

Type 2 diabetes (T2DM) is a silent disease with devastating consequences. With increasing earlier onset of T2DM across the globe, particularly in Asia, the younger ages at which T2DM is diagnosed translates into an extended disease duration and an escalating rate of complications [1–3]. Life expectancy of diabetic patients is generally shorter than their nondiabetic counterparts [4], because diabetes is a well-established, independent risk factor for a wide range of vascular diseases, as well as nonvascular diseases, including cancers [4,5].

Macrovascular complications associated with diabetes are the leading cause of death among patients with diabetes [6], and diabetes confers about a twofold excess risk for coronary heart disease and ischemic stroke [5]. However, diabetes-related microvascular complications, namely nephropathy, retinopathy, and neuropathy, account for the excess morbidity, which negatively impacts on patients' quality of life and poses a huge burden on the health system and resources [6,7]. Moreover, experiencing microvascular complications is associated with a greater risk of macrovascular complications, including coronary heart disease and cerebrovascular diseases [7,8]. Since prevention is more cost-effective than the treatment of diabetes complications, there is indeed a pressing need for more evidence to support efficacious preventative strategies that could delay or avert the development and progression of microvascular complications in diabetic populations. Here, we review the evidence from clinical trials in the prevention of diabetic complications, with a particular focus on the preventive strategies of diabetic microvascular complications.

Diabetic nephropathy

Diabetes is the single leading cause of end-stage renal disease worldwide and accounts for approximately 40% of patients requiring dialysis [9]. Due to the diversity of genetic and environmental factors, the prevalence and incidence of diabetic nephropathy varies across different ethnic groups. Diabetic kidney disease has emerged as an important cause of morbidity and mortality in diabetes, particularly in Asia where the prevalence of diabetic nephropathy is alarmingly high (up to 60%) when compared to the United States and Europe [1,10]. Diabetic nephropathy is particularly prevalent in Asian diabetic populations (40% have microalbuminuria and 20%

have macroalbuminuria) [10], and occurs in 20–40% of diabetic patients in the United States [11]. Diabetic patients with nephropathy and reduced renal function, as measured by estimated glomerular filtration rate (eGRF), are especially vulnerable to developing cardiovascular events and all-cause mortality [12].

Intensive glycemic control in the prevention of diabetic nephropathy

It has been well recognized that good glycemic control is crucial to prevent diabetic nephropathy in both type 1 and type 2 diabetic patients. The Diabetes Control and Complications Trial (DCCT) showed that tight glycemic control, close to normoglycemia, delays the onset and slows the progression of diabetic nephropathy, retinopathy, and neuropathy in type 1 diabetes [13]. The DCCT randomly assigned 1441 patients with type 1 diabetes (mean age 27 ± 7 years) to intensive or conventional therapy, treating them for a mean of 6.5 years between 1983 and 1993 [13]. After a mean follow-up of 17 years (93% were followed until February 2005 during the observational Epidemiology of Diabetes Interventions and Complications study (EDIC)), type 1 diabetic patients in the intensive treatment group had a significantly lower risk of experiencing diabetic nephropathy (microalbuminuria and albuminuria), cardiovascular and myocardial infarction compared to those in the conventional therapy group [14].

In keeping with the findings of the DCCT, the United Kingdom Prospective Diabetes Study (UKPDS) [15] (a 10-year randomized study in the UK including 3867 newly diagnosed type 2 diabetic patients) and the Kumamoto Study [16] (a 6-year randomized study in Japan including 110 type 2 diabetic patients with poor glycemic control), also showed that intensive glycemic control reduces the risk of microvascular complications, including diabetic nephropathy [15,16]. In the Kumamoto study, 110 Japanese type 2 diabetic patients with poor glycemic control were randomized to either the multiple insulin injection group or the conventional insulin injection group to evaluate the impact of intensive treatment versus conventional treatment, on both primary and secondary prevention of diabetic nephropathy, retinopathy, and neuropathy (mean glycated hemoglobin (HbA1c) at baseline was $8.9 \pm 1.8\%$ and $9.2 \pm 1.8\%$ in the primary prevention group; $9.0 \pm 1.9\%$ and $9.4 \pm 1.8\%$ in the secondary prevention group) [16]. After 6 years of treatment, diabetic patients in the intensive treatment group (mean HbA1c $7.1 \pm 1.1\%$) had a significantly reduced risk of suffering the onset and progression of diabetic nephropathy, as well as other diabetes-related microvascular complications, namely retinopathy and neuropathy, compared to those in the conventional treatment group (mean HbA1c $9.4 \pm 1.5\%$) [16]. The cumulative percentage of the development and the progression in nephropathy in the primary prevention cohort and secondary prevention cohort were 7.7% and 28.0%, and 11.5%

and 32.0% in the intensive and conventional group, respectively [16]. In the UKPDS, 3867 newly diagnosed type 2 diabetic patients (median age 54 years, interquartile range 48–60 years) were randomly assigned to the intensive treatment or conventional treatment group. After 10 years, diabetes patients in the intensive group (mean HbA1c 7%) had a 25% risk reduction in the development of microvascular complications compared to the diabetic patients in the conventional group (mean HbA1c 7.9%) [15]. The 10-year post-trial follow-up of the UKPDS [17], similar to the long-term follow-up data of the DCCT [14] and the Kumamoto study [18], demonstrated the beneficial effect regarding the legacy of intensive glycemic control in delaying the onset and progression of microvascular complications.

Since then, a number of randomized controlled clinical trials, including the ADVANCE trial (Action in Diabetes and Vascular Disease: Preterax and Diamicron Modified Release Controlled Evaluation) [19], ACCORD (Action to Control Cardiovascular Risk in Diabetes) [20], VADT (Veteran Affairs Diabetes Trial) [21], and the VA (Veterans Affairs) Feasibility Trial [22] were conducted, which consistently reaffirm that intensive glucose control reduces the risk of diabetic nephropathy among type 2 diabetic patients (Table 39.1). In the ADVANCE study [19], 11,140 type 2 diabetic patients with poor glycemic control (median HbA1c at baseline 7.2%) were recruited from 20 countries spanning Asia (37%), Australasia (13%), Europe (46%), and North America (4%). The study subjects had a mean disease duration of 8 years and a mean age of 66 years. The eligible subjects were randomly assigned to the intensive treatment group, using glicalzide (modified release) plus other glucose-lowering drugs aiming to keep HbA1c $\leq 6.5\%$, or to the conventional treatment group with an HbA1c goal according to the local guidelines. After a median follow-up of 5 years, the mean HbA1c was lower in the intensive group than in the conventional treatment group (6.5% vs. 7.3%), and the intensive group was associated with a 21% reduction in renal events including new or worsening nephropathy ($p = 0.006$) and a 9% reduction of new-onset microalbuminuria ($p = 0.02$) [19]. In the ACCORD study [20], 10,251 type 2 diabetic patients were recruited in the United States and Canada (mean age of 62 years, mean disease duration of 10 years, median HbA1c at baseline 8.1% with the goal of HbA1c for the intensive arm of <6% vs. 7–7.9% for the conventional group). The study was prematurely terminated after 3.7 years of treatment due to a higher mortality rate in the intensive treatment group. The results of the ACCORD study showed that there was fewer renal events in the intensive glycemic arm [20]. In comparison, the VADT [21] and VA Feasibility Trial [22] were on a smaller scale with 1791 and 153 male patients with T2DM studied, respectively. The results from both the VADT [21] and VA Feasibility Trial [22] support the finding that intensive glycemic control reduces the risk of diabetic nephropathy compared to conventional treatment.

Table 39.1 Randomized controlled trials examining intensive glycemic control and risk of microvascular complications in diabetic patients.

Blood pressure control, renin-angiotensin-aldosterone system and prevention of diabetic nephropathy

Apart from intensive glycemic control, achieving tight control of blood pressure and blockade of the renin-angiotensin-aldosterone system (RAAS) are the cornerstones in preventive strategies of diabetic kidney disease, as demonstrated by a number of clinical trials [23].

In addition to demonstrating the beneficial effect of tight glycemic control, the UKPDS also clearly shows that tight blood pressure control (aiming at blood pressure <150/85 mmHg vs. <180/105 mmHg with either angiotensin-converting enzyme inhibitor or a beta-blocker) reduces the risk of developing microvascular complications by 37% [24]. For every 10 mmHg reduction in systolic blood pressure, there is a 12% risk reduction in any diabetes-related complications [25]. The beneficial effect

of blood pressure control is further supported a number of clinical trials, including the RENAAL (Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan) study [26] which showed that every 10 mmHg increase in baseline systolic blood pressure was associated with an increased risk of end-stage renal disease (ESRD) or death by 6.7%, after adjusting for potential confounders including urinary ACR, serum creatinine, serum albumin, hemoglobin, and HbA1c [27].

There is little doubt about the role of RAAS blockade in conferring protective effects in patients with diabetic nephropathy, which is independent of blood pressure lowering. The IDNT (Irbesartan Diabetic Nephropathy Trial) [28] and RENAAL [26] study are the landmark trials that clearly demonstrated the renoprotective effects of both angiotensin-converting enzyme inhibitor (ACEI) and angiotensin II-receptor blocker (ARB). In the IDNT study, a total of 1715 patients with hypertension

and diabetic nephropathy were randomized to either irbesartan (300 mg daily) or placebo (mean duration of follow-up was 2.6 years) [28]. Irbesartan treatment was associated with a 33% risk reduction in doubling of serum creatinine and a 23% risk reduction in ESRD, when compared to the placebo group [28]. In the RENAAL study, a total of 1513 patients with T2DM and diabetic nephropathy were randomized to either losartan (50 to 100 mg daily) or placebo [26]. After a mean treatment of 3.4 years, patients in the losartan group had a 25% risk reduction in the incidence of doubling of serum creatinine level and 28% risk reduction in the incidence of ESRD, compared to the placebo group [26]. The subgroup analysis of the RENAAL study also showed that the losartan conferred an even greater risk reduction in Asian diabetic patients with a 35% risk reduction in the primary composite endpoint composed of a doubling of serum creatinine, ESRD, and all-cause mortality [29].

Regarding the comparative effectiveness of ACEI versus ARB in secondary prevention of renal deterioration in patients with diabetic nephropathy, data from the DETAIL (Diabetics Exposed to Telmisartan and Enalapril) study did not support any advantage of one over the other [30]. Recently, the ROADMAP (Randomized Olmesartan and Diabetes Microalbuminuria Prevention) trial showed clinical evidence of ARB in the primary prevention of diabetic nephropathy. In ROADMAP, olmesartan, an angiotensin II-receptor blocker (ARB), is shown to delay onset of microalbuminuria in patients with T2DM [31]. The ROADMAP study included 4447 type 2 diabetic patients (mean age 57.7 years, 46.1% men) randomly assigned to receive olmesartan or placebo for a median duration of 3.2 years. There was a 23% risk reduction of development of microalbuminuria in type 2 diabetic patients in the olmesartan group [31].

Despite optimal control of glycemia, blood pressure, lipids and the use of RAAS blockers, the renal function of some diabetic patients with nephropathy continues to deteriorate and not all patients respond to treatment of ACEI or ARB. Since 40% of angiotensin II is produced by other non-ACE pathways, such as chymase, which may be substantially more active in diabetic patients [32], this incomplete blockade of RAAS may explain the observation that some diabetic patients continue to have rapid renal deterioration despite treatment with ACEI or ARB, and in addition to those treatment nonresponders. Theoretically, treatment with ARB may result in a more complete blockade of the RAAS, and dual blockade of the RAAS with both ACEI and ARB has been advocated to achieve better renal protection. However, the result of the ONTARGET (Ongoing Telmisartan Along and in Combination with Ramipril Global Endpoint Trial) [33] is disappointing with a worsening of renal outcomes after dual blockade of RAAS. ONTARGET is a mega trial which included 25,620 patients with established atherosclerotic vascular disease or with diabetes with end-organ damage and randomized them to ramipril ($n = 8576$), telmisartan ($n = 8542$), or a combination of both drugs ($n = 8502$) with a median follow-up of 56 months [33]. The event rate for primary renal outcome (dialysis, doubling of serum creatinine and death) was similar

for the telmisartan and ramipril groups but was increased in patients treated with dual blockade of ACEI and ARB [33]. The ORIENT (Olmesartan Reducing Incidence of Endstage Renal Disease in Diabetic Nephropathy Trial) [34] also failed to show that the use of ARB in combination with ACEI improves renal outcomes in patients with diabetic nephropathy. ORIENT recruited Asian type 2 diabetic patients (377 Japanese and 200 Chinese) with overt diabetic nephropathy, who were either on (73.5% in total cohort and 100% in Chinese participants) or not on baseline ACEI treatment, to receive either olmesartan ($n = 288$) or placebo ($n = 289$) over a mean treatment duration of 3.2 years [34]. The primary composite outcome (doubling of serum creatinine, endstage renal disease and death) was not significantly different in the olmesartan and placebo groups [34]. Of note, the predefined secondary cardiovascular endpoint was positive in ORIENT study, similar to a study involving Valsartan or another one involving spironolactone which showed that dual blockade was cardioprotective.

Other new approaches to achieve complete blockade of RAAS have been attempted in the treatment of patients with diabetic nephropathy. Aldosterone receptor antagonists, such as spironolactone, have been shown to further reduce proteinuria when added to an ACEI or ARB in treating diabetic patients with nephropathy. However, only small-scale and short-term clinical trial evidence is available [35,36] and thus long-term clinical benefits are yet to be shown.

Aliskiren, the first direct renin inhibitor that is orally active, has been approved for the treatment of hypertension since 2007. Aliskiren differs from ACEI and ARB in blocking the first and rate-limiting step in the RAAS, leading to a suppression of all RAAS hormones, including plasma renin activity but not plasma renin concentration. Therefore, aliskiren has the theoretical advantage of overcoming incomplete RAAS blockade with ACEI and ARB, and may translate into improved clinical benefits in treating patients with diabetic nephropathy. In the AVOID (Aliskiren in the Evaluation of Proteinuria in Diabetes) study [37], 599 type 2 diabetic patients with nephropathy, hypertension, and treated with 100 mg daily losartan at baseline, were randomized to receive 6 months therapy of add-on aliskiren or placebo. Patients in the aliskiren group had a 20% reduction of urinary ACR compared to the placebo group [37]. Following this encouraging preliminary data from AVOID, the ALTITUDE (Aliskiren Trial in Type 2 Diabetes Using Cardio-Renal Endpoints) [38] trial was designed to examine whether dual RAAS blockade with aliskiren in combination with an ACEI or ARB in patients with type 2 diabetic nephropathy and renal impairment would reduce cardiorenal endpoints. To the dismay of many clinicians and researchers, ALTITUDE was prematurely terminated due to the increased incidence of nonfatal stroke, renal complications, hyperkalemia, and hypotension after 18–24 months of follow-up [39]. Aliskiren is subsequently not recommended by regulatory authorities for prescription with ACEI and ARB in patients with T2DM and renal impairment. Pending disclosure of the full results, the early termination of

the ALTITUDE trial further highlights the concerns regarding the safety issues of complete blockade of RAAS.

Other therapies for preventing diabetic nephropathy

Dyslipidemia is known to be associated with diabetic vascular complications including nephropathy. In a substudy of the FIELD (Fenofibrate Intervention and Event Lowering in Diabetes) study [40], reduced albuminuria and a slower decline of eGFR over 5 years were observed, suggesting fenofibrate may prevent the onset and progression of diabetic nephropathy in type 2 diabetic patients, despite an initial increase in plasma creatinine levels, which was reversible [41]. The FIELD study was a multinational study including 9795 type 2 diabetic patients (mostly White/Caucasian) aged 50–75 years (mean age 62 years) randomly assigned to receive fenofibrate 200 mg daily or placebo treatment for an average of 5 years, with the aim to assess whether lipid-lowering therapy could reduce macro- and microvascular complications in type 2 diabetic patients [40].

Since the pathogenesis of diabetic nephropathy is known to be associated with abnormalities of renal nitric oxide (NO) generation, inhibition of phosphodiesterase 5 (PDE5) may have a renoprotective potential in patients with diabetic nephropathy. PDE5 is an enzyme that degrades cyclic guanosine monophosphate (cGMP), an intracellular mediator generated following the activation of soluble guanylate cyclase by NO. The inhibition of PDE5 thus leads to the elevation of intracellular cGMP levels. Many of the biologic actions of NO are mediated by cGMP, including the relaxation of vascular smooth muscle. Data from animal models showed that sildenafil, a PDE5 inhibitor, decreased albuminuria, attenuated glomerular hyperfiltration and resulted in a reduction of glomerular hypertrophy and glomerulosclerosis score, and ameliorated oxidative and inflammatory renal injuries in type 2 diabetic rats [42,43].

More novel therapies have recently begun to emerge, with the vast majority focusing upon the anti-inflammatory pathways, as well as kidney regeneration, stem cell growth factors, and so on. Yet, these novel therapies are still at the infancy stage of development, but may help to shed light on and hope for future treatments for T2DM.

Given that diabetes is a multifaceted disease, an intensified multifactorial intervention, incorporating a combination of tightly controlled glycemia, optimal blood pressure control, the use of RAAS blocker, and lipid-lowering agents, plays a pivotal role in the primary and secondary prevention of diabetic nephropathy. The STENO study clearly demonstrated the importance of this all-encompassing approach in intensified management of risk factors in treating type 2 diabetic patients [44]. In the STENO-2 study [44], 160 type 2 diabetic patients with microalbuminuria were randomized to receive either intensive therapy (multiple drugs for tight glycemia, blood pressure, and lipid control as well as aspirin) or conventional therapy. The mean treatment of 7.8 years was followed by a mean observational period of 5.5 years. Diabetic patients in the intensive treatment group experienced a reduced progression to endstage renal disease and required less retinal photocoagulation compared to the conventional group [44]. The clinical benefit of a structured care model in reducing renal endpoints is further supported by the SURE study [45] (Figure 39.1).

Diabetic neuropathy

Diabetic neuropathy is amongst the most common of the long-term complications of diabetes affecting up to 50% of patients [46]. The epidemiology and natural history of diabetic neuropathy, both somatic and autonomic, remain poorly defined, partly because existing studies use different and variable criteria to diagnose diabetic neuropathy. Diabetic neuropathy, in combination with the occurrence of other complications, such as peripheral vascular disease, can result in diabetic foot disease and is the leading cause of amputation.

Role of metabolic and blood pressure control in diabetic neuropathy

The DCCT clearly demonstrates the beneficial effects of intensive glycemic control in delaying the onset and progression of diabetic neuropathy in T1DM [13]. The long-term follow-up in the EDIC trial of subjects originally from the DCCT cohort, supports the unique legacy effect of prior tightly controlled blood glucose in delaying the onset of incident neuropathy [47] including cardiac autonomic neuropathy [48], an important cause of sudden death and one of the most overlooked complications of diabetic patients.

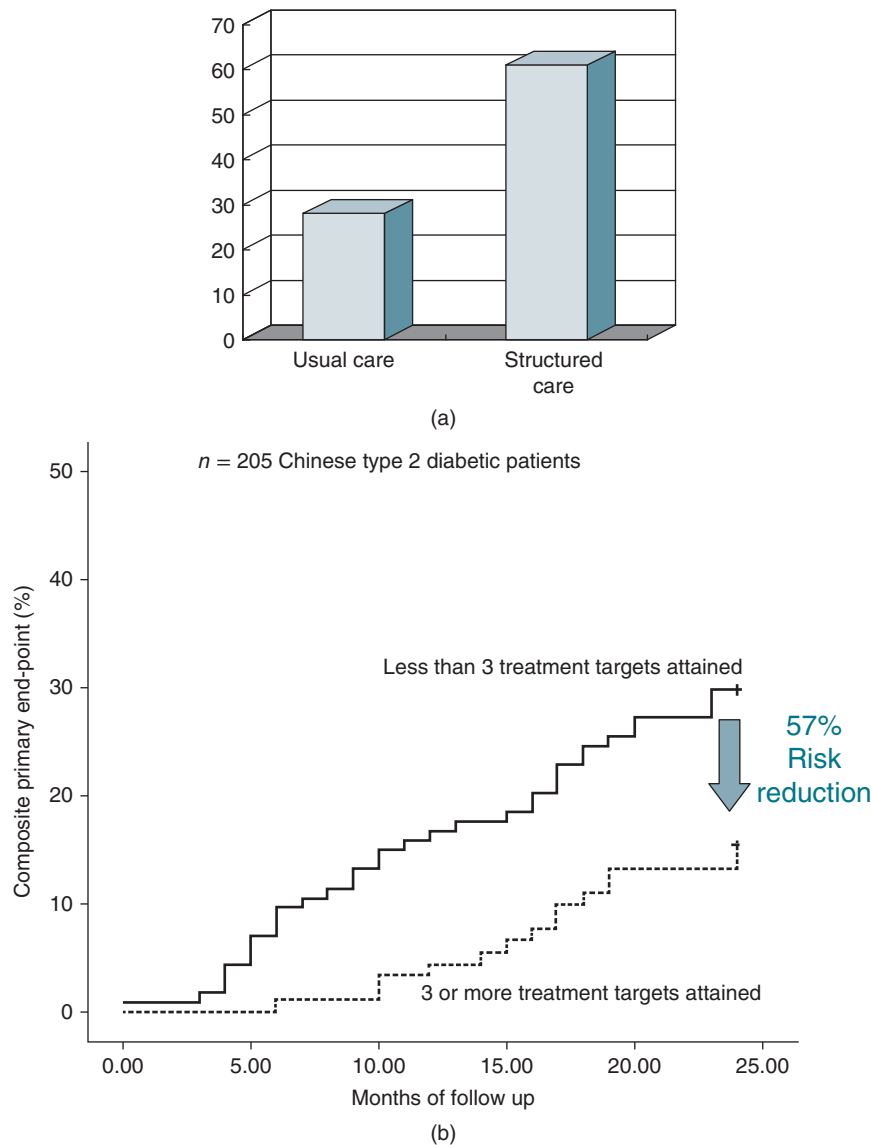
In the UKPDS, there was no significant difference in diabetic neuropathy, as assessed clinically by knee (11 vs. 12%, $p = 0.42$) and ankle reflexes (35 vs. 37%, $p = 0.60$), between the intensive and conventional treatment groups [17]; autonomic neuropathy was also assessed by R–R intervals measured on electrocardiograms at expiration and inspiration on deep breathing for five cycles, change in R–R interval on standing, and, in men, self-reported erectile dysfunction [15]. Likewise, the incidence of new or worsening neuropathy was similar in type 2 diabetic patients in both the intensive and standard treatment groups in the ADVANCE study [19]. By contrast, results from the Kumamoto [16] and ACCORD [20] studies support the role of tight glycemic control in the prevention of diabetic neuropathy (Table 39.1). In the Kumamoto study, intensive glycemic control was shown, in both the initial study and long-term follow-up, to delay the onset and impede the progression of diabetic neuropathy, diabetic nephropathy, and retinopathy [18,49]. Regarding blood pressure control, although the ABCD trial (Appropriate Blood Pressure Control on Diabetes) [50] failed to show intensive blood pressure control reduced diabetic neuropathy or retinopathy compared to moderate blood pressure control (a 5-year study including 470 hypertensive diabetes patients with a goal to maintain diastolic blood pressure ≤ 75 mmHg vs. 80–89 mmHg), the STENO-2 study showed that the progression of autonomic neuropathy, as measured by the R–R


Figure 39.1 The SURE (Effects of Structured versus Usual Care on Renal Endpoints in type 2 diabetes) study [45] showed a significantly higher percentage of diabetic patients in the structured care group achieved at least 3 predefined treatment targets compared to diabetic patients randomized to the usual care group(61% vs. 28%, $p < 0.001$) (a). Treatment targets were defined as HbA1c <7%, blood pressure <130/80 mmHg, LDL cholesterol <2.6 mmol L^{-1}, triglyceride <2 mmol L^{-1}, and persistent treatment with renin-angiotensin blockers. Patients who attained ≥3 treatment targets had reduced risk of primary endpoint (death and/or renal endpoint, i.e., serum creatinine >500 μmol L^{-1} or dialysis) compared to those who attained ≤2 targets (relative risk 0.43; 95% CI 0.21–0.86) (b).

interval on an electrocardiogram during paced breathing and in an orthostatic hypotension test, was less in the intensive group compared to the conventional group (39 patients vs. 52 patients, $p = 0.004$) [44]. However, there was no difference in the progression of peripheral neuropathy, as measured by biothesiometer, between intensive and conventional groups [44].

Strategies in preventing diabetic neuropathy: from pathophysiology to prevention

The underlying mechanisms leading to the development of diabetic neuropathy are still not completely understood [46].

Nonetheless, there is a large body of evidence suggesting that multiple metabolic pathways may interact and contribute to nerve damage [46]. Hyperglycemia activates several metabolic processes including the polyol pathway, oxidative stress, protein kinase C-beta (PKC-β), formation of advanced glycation endproducts (AGEs), which in turn act on specific receptors (RAGEs) inducing monocytes and endothelial cells to increase production of cytokines and adhesion molecules [46]. Moreover, growth factors (e.g. ciliary neuropathic factor, insulin-like growth factors, vascular endothelial growth factors) and autoimmune immunoglobulin may also play a role in the prevention of

diabetic neuropathy in *in vitro* studies. Therapies targeting these pathways have been attempted in animal models and small-scale human studies, but evidence from clinical trials to support the use of these novel agents is still lacking. For instance, aldose reductase is the key enzyme in the polyol pathway, and the blockade of this enzyme prevents the generation of neurotoxic sugar alcohols, for example sorbitol. Aldose reductase inhibitors have been studied in a number of preliminary trials, but many had significant methodological flaws [51]. From a meta-analysis including thirty-two randomized controlled trials, there was no significant difference between aldose reductase inhibitors and placebo in the treatment of diabetic polyneuropathy [51]. However, in another meta-analysis including ten trials which aimed to explore the role of aldose reductase inhibitors in the treatment of diabetic cardiovascular autonomic neuropathy, aldose reductase inhibitors were effective especially in mild or asymptomatic cases with minimal adverse effects except Tolerestat [52].

Diabetic retinopathy

Diabetic retinopathy is the most common cause of blindness in the working age group. Similar to other diabetic microvascular complications, one of the major challenges of preventing diabetic retinopathy is the extremely long latent and silent developmental phase of the disease, where treatment must be initiated before irreversible and devastating consequences occur. Therefore, regular screening of fundi is mandatory in the holistic management of diabetes.

Glycemia, blood pressure, dyslipidemia, and diabetic retinopathy

Similar to the beneficial effects on diabetic nephropathy and neuropathy in both the short and long term, intensive glycemic control is also vital in preventing the development and progression of diabetic retinopathy in type 1 diabetic patients as demonstrated by the DCCT and the subsequent 10-year follow-up study [13,53]. This finding further supports the "metabolic memory" phenomenon, as there was a reduced risk of diabetic retinopathy in the intensive treatment group of type 1 diabetic patients, which persisted for 4 years after completion of the DCCT, despite similar HbA1c levels in both the intensive and conventional arms [53].

In the UKPDS, diabetic patients in the intensive treatment group had a 29% risk reduction of retinal photocoagulation compared to those in the conventional group (relative risk 0.71; 95% CI 0.53–0.96; $p = 0.0031$) [15]. The UKPDS also demonstrates that tight blood pressure control significantly reduces the risk for proliferative retinopathy by 35% [24]. From the results of DIRECT (DIabetic Retinopathy Candesartan Trials), a randomized, double-blinded, placebo-controlled trial in 309 centers worldwide, including 1421 type 1 diabetic patients aged 18–50 years [54], candesartan, an ARB, reduces the incidence of diabetic retinopathy by 35% (hazard ratio 0.65;

95% CI 0.48–0.87; $p = 0.0034$) but not retinopathy progression (hazard ratio 1.02; 95% CI 0.80–1.31; $p = 0.85$).

Both high levels of cholesterol and triglycerides have been shown to predict increased rates of diabetic retinopathy. Lipid-lowering agents may protect against retinopathy in diabetic patients by ameliorating oxidative stress and reducing cytokines [55]. The beneficial effects of lipid-lowering agents for the management of diabetic retinopathy are well demonstrated by the FIELD study [40] and the ACCORD Eye Substudy [56]. In the FIELD study, diabetic patients who had poorer glycemic or blood pressure control required laser therapy more frequently. The requirement for first laser therapy was lower in the fenofibrate group compared to the placebo group (hazard ratio 0.69; 95% CI 0.56–0.84; $p = 0.0002$) [40]. Nonetheless, the mechanism of the beneficial effect of fenofibrate therapy in diabetic retinopathy is unclear, as the effect is not related to the plasma concentrations of lipids. In the ACCORD study, intensive glycemic control and combination treatment with fenofibrate for intensive dyslipidemia therapy, but not intensive blood pressure control, reduced the progression rate of diabetic retinopathy [56]. A subgroup of 2856 type 2 diabetic patients in the ACCORD study was evaluated for the effect of intensive treatment for glycemia and dyslipidemia (fenofibrate 160 mg daily plus simvastatin or placebo plus simvastatin), or systolic blood pressure control treatment (target at <120 vs. <140 mmHg) using two comprehensive, standardized eye examinations conducted by a study ophthalmologist or optometrist, along with fundus photography at baseline and year 4 of follow-up [56]. After 4 years of follow-up, the progression rates of diabetic retinopathy were significantly lower in the intensive glycemic arm (7.3% vs. 10.4%; adjusted odds ratio 0.67; 95% CI 0.51–0.87; $p = 0.003$). The risk of diabetic retinopathy progression was also reduced in the intensive dyslipidemia group when compared to the conventional group (6.5% vs. 10.2%; adjusted odds ratio 0.60; 95% CI 0.42–0.87; $p = 0.006$), while there was no difference between intensive blood pressure and conventional groups [56]. In contrast to the results from the DCCT, UKPDS, FIELD, and ACCORD studies, the ADVANCE study failed to show any difference in the incidence of retinopathy (defined as new or worsening retinopathy or visual deterioration) [19].

Again, the STENO-2 study [44] confirms the protective effect of a combination of intensive therapies including blood glucose, blood pressure and lipid control in the prevention of diabetic retinopathy.

Anti-vascular endothelial growth factor (VEGF) and other treatments in the prevention of diabetic retinopathy

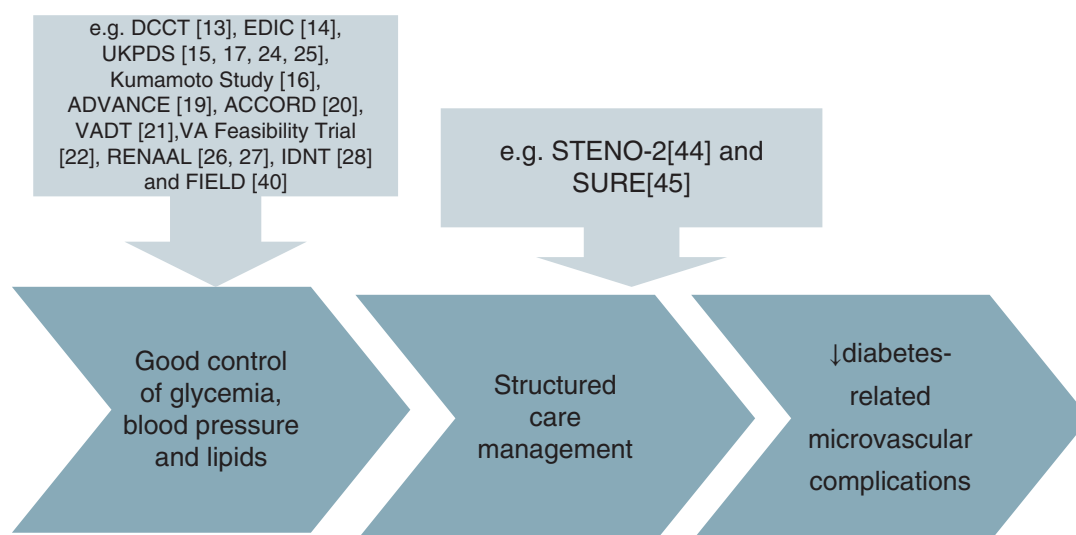
Since vascular endothelial growth factor (VEGF) has been demonstrated to be extensively involved in the development and progression of diabetic retinopathy, notably diabetic macular edema, VEGF inhibitors may provide an alternative therapeutic approach to retinal laser photocoagulation in the treatment of advanced diabetic retinopathy. A meta-analysis


Figure 39.2 Evidence from clinical trials supporting structured care management and good control of glycemia, blood pressure, and lipids in primary and secondary prevention of diabetes-related microvascular complications.

of randomized controlled trials in the evaluation of the therapeutic effects of ranibizumab (Lucentis), a recombinant human monoclonal antibody inhibiting VEGF, has shown that ranibizumab is more efficient in reducing the amount of retinal thickening than laser treatment [57]. Recently, ranibizumab was approved for the treatment of diabetic macular edema by the European Medicines Agency and the United States Food and Drug Administration (FDA) [58,59]. Anti-inflammatory agents, including corticosteroid therapy, have also been shown in randomized clinical trials to improve visual acuity in diabetic patients with retinopathy complications [59]. Since oxidative stress is considered to be one of the major contributors to the development of diabetic retinopathy, antioxidants may also play a role in the prevention of diabetic retinopathy, but definitive evidence from clinical trials is still lacking. The role of VEGF inhibitors, anti-inflammatory agents and antioxidants in the primary prevention of diabetic retinopathy in high-risk patients therefore remains to be elucidated.

Conclusion

Good control of glycemia, blood pressure, and dyslipidemia are pivotal in the primary and secondary prevention of diabetic microvascular complications as evident from the wealth of data from clinical trials. Structured and comprehensive care is important for management of T2DM, a complex and multifaceted disease (Figure 39.2). Given the growing burden of diabetes and its complications, there is a need for more efficacious treatment strategies to prevent the development and progression of diabetic complications. Future clinical trials should strive to provide conclusive clinical evidence to support or reject the use of novel drugs and treatment regimens to effectively manage diabetes complications.

Management of diabetes: diet, exercise and drugs

CHAPTER 40

Dietary management of diabetes mellitus in Europe and North America

Jim I. Mann[1,2] and Alexandra Chisholm[1]

[1] Department of Human Nutrition, University of Otago, Dunedin, New Zealand
[2] Obesity Research Centre, University of Otago, Dunedin, New Zealand

Key points

- Dietary management is a cornerstone of treatment for patients with type 1 and type 2 diabetes (T1DM, T2DM). Benefits are derived principally from naturally occurring foods rather than supplements or functional foods.

- In order to achieve compliance with dietary advice, specific goals should be individually negotiated with the patient. Whenever possible such advice should be given by a counselor specifically trained in nutrition management of diabetes and associated comorbidities.

- For patients with T1DM who are not overweight, basing dose of rapidly acting insulin on carbohydrate content of meals and snacks (carbohydrate counting) as well as preprandial glucose levels, may be expected to improve overall glycemic control.

- For those with T2DM who are overweight, controlling energy intake to achieve weight reduction is likely to improve glycemic control to the extent that will obviate or delay the need for oral agents or insulin. If already on drug therapy, intensified dietary treatment may be expected to produce further improvement in glycemic control and often dose reduction. Cardiovascular risk factors also improve.

- All people with diabetes should aim to achieve intakes of saturated and *trans* unsaturated fatty acids which are well below 10% total energy and dietary salt to below $6\,g\,d^{-1}$ to reduce cardiovascular risk.

- A wide range of intakes of carbohydrate (45–60% total energy), *cis* monounsaturated fatty acids (10–20% TE), and protein (10–20% TE), are acceptable and will depend upon personal preference, extent and nature of metabolic derangement and degree of adiposity. However, carbohydrates should be derived principally from a range of vegetables, fruits, legumes, and wholegrains which are rich in dietary fiber and have a low glycemic index.

- Polyunsaturated fatty acids may be increased from current low levels to a maximum of 10% TE and should be derived from sources of both *n*-3 and *n*-6 fatty acids.

- The wide range of acceptable intakes enables compatibility with the many different dietary patterns of Europe and North America.

Introduction

Dietary modification is the mainstay of treatment for type 2 diabetes (T2DM). Despite the usually progressive nature of the disease, many newly diagnosed patients with T2DM who comply with dietary advice will show improvement in glycemic control to an extent that will obviate or delay the need for oral agents and insulin. For those who require drug therapy, attention to dietary advice can be expected to further improve glycemic control [1]. In type 1 diabetes (T1DM) dietary advice aims to minimize excessive postprandial glycemia and fluctuations in blood glucose levels. Avoidance of hypoglycemia is a particularly important aim. In all people with diabetes, nutrition therapy is also designed to reduce the risk of long-term complications both by improving glycemic control and by reducing other risk factors (notably dyslipidemia and raised blood pressure levels) for vascular disease. Dietary advice in relation to choices about types of foods for those with T2DM and T1DM is similar, and the major principles resemble those for entire populations at high risk of CHD. There is therefore no need for diabetic patients to be given meals that differ from those eaten by the rest of the family. Dietary recommendations for people with diabetes have been made in many countries. It is reassuring that those of the Diabetes and Nutrition Study Group of the European Association for the Study of Diabetes (DNSG), representing the majority of European countries [2] and the American Diabetes Association (ADA) [3] are generally consistent. These two organizations were amongst the first to issue evidence-based guidelines for the nutritional management of people with diabetes. Any points of difference between the two sets of recommendations are indicated in the text below. Table 40.1 summarizes the basic principles of diabetic dietary recommendations.

Table 40.1 Key aspects of the current recommendations for diabetic diet and lifestyle

Dietary energy and body weight	Achieve and/or maintain BMI of 18.5–25 kg m^{-2} or if obese, a reduction of at least 5% starting weight Diet and exercise important
Dietary fat	Saturated plus *trans* unsaturated fatty acids: < well below 10% total energy Polyunsaturated fatty acids: 6–10% total energy Monounsaturated fatty acids: 10–20% total energy Total fat: <35% total energy (if overweight <30%) Oily fish, soybean and rapeseed oil, nuts and green leafy vegetables to provide *n*-3 fatty acids Cholesterol: <200 g d^{-1}
Carbohydrate	Total carbohydrate: 45–60% total energy, influenced by metabolic characteristics Vegetables, fruits, legumes, and cereal-derived foods preferred
Dietary fiber and glycemic index	Naturally occurring foods rich in dietary fiber are encouraged Ideally dietary fiber intake should be more than 40 g d^{-1} (or 20 g/1000 kcal d^{-1}), half-soluble (lesser amounts also beneficial) Five servings per day of fiber-rich vegetables and fruit and four or more servings of legumes per week help to provide minimum requirements Cereal-based foods should be wholegrain and high in fiber Carbohydrate-rich low-glycemic-index foods are suitable choices, provided other attributes are appropriate
Sucrose and other free sugars	If desired and blood glucose levels are satisfactory, free sugars up to 50 g d^{-1} may be incorporated into the diet Total free sugars should not exceed 10% total energy (less for those who are overweight)
Protein and renal disease	Total protein intake at lower end of normal range (0.8 g kg^{-1} d^{-1}) for type 1 patients with established nephropathy For all others, protein should provide 10–20% total energy
Vitamins, antioxidant nutrients, minerals, and trace elements	Increase foods rich in tocopherols, carotenoids, vitamin C and flavonoids, trace elements and other vitamins Fruits, vegetables, wholegrains rather than supplements recommended Restrict salt to less than 6 g d^{-1} (less than 2.3 g sodium)
Alcohol	Up to 10 g for women and 20 g for men per day is acceptable for most people with diabetes who choose to drink alcohol Special precautions apply to those on insulin or sulfonylureas, those who are overweight and those with hypertriglyceridemia
Special "diabetic" foods, or functional foods and supplements	Nonalcoholic beverages sweetened with non-nutritive sweeteners are useful Other special foods not encouraged No particular merit of fructose and other "special" nutritive sweeteners over sucrose
Families	Most recommendations suitable for whole family

Total energy intake

The majority of people with T2DM are overweight and usually have other features of the metabolic syndrome (raised levels of insulin, raised triglyceride and low high-density lipoprotein (HDL) levels, hypertension, high levels of uric acid, and elevated levels of plasminogen activator inhibitor 1 in addition to hyperglycemia. Even modest weight reduction is associated with a reduction in insulin resistance, and hepatic glucose production, and perhaps an improvement in islet β-cell function. A reduction in blood glucose may be seen with reduced energy intake even before weight loss occurs. In addition to the resultant improvement in overall glycemic control, as measured by HbA1c, many of the other abnormalities associated with the metabolic syndrome, notably dyslipidemia and raised blood pressure, also improve with weight loss. The improvement in metabolic parameters associated with weight loss is seen not only in the early stages of the disease but has also been demonstrated in patients in whom glycemic control was considered to have been optimized on standard treatment regimens involving insulin and or oral hypoglycemic agents [1].

It is generally accepted that total energy (TE) should be reduced so that BMI moves toward the desirable range (20–25 kg m^{-2}). Some Asian populations which are well represented in Europe and North America have a relatively high proportion of visceral fat and central adiposity and an even higher risk of cardiovascular disease than European populations with diabetes. For them a slightly lower BMI is generally regarded as optimal. However, despite advice and support many people with T2DM are unable to achieve this target. It is important therefore to set realistic goals for weight reduction and to provide intermediate as well as long-term targets.

A sustained weight loss of 1–2 kg per month with the aim of achieving a long-term weight loss of 5–7% of starting weight is a reasonable goal for most patients. This can usually be achieved by a reduction of about 500 kcal below that required for weight maintenance. Weight loss may lead to greater improvements in cardiac risk factors in individuals with a high waist circumference but all patients with excessive adiposity, regardless of distribution, should be advised to lose weight. Regular physical activity is generally considered to enhance weight loss and to be particularly important in weight maintenance when targets have been achieved. Behavior modification techniques are an important component of weight loss programs.

A wide range of "diets" of varying macronutrient composition (e.g. low carbohydrate, high protein, high carbohydrate-high fiber, high fat) and dietary patterns (e.g. Mediterranean) have been promoted as being the most appropriate options for achieving weight loss in people with diabetes. Appropriate distribution of macronutrients is considered in the sections which follow. However, it should be noted that there is no clinical trial evidence that in the medium- to long-term, any one dietary approach has advantages over the others with regard to either weight loss or clinical outcomes [4,5]. It is particularly noteworthy that diets very low in carbohydrate may be associated with increases in LDL-cholesterol and generally involve the elimination of foods that are important sources of fiber and essential micronutrients [5]. Carbohydrate intakes below about 130 g d^{-1} are not advised.

The most appropriate approach to achieving weight reduction depends upon the requirements of individual patients. For some it may be sufficient to advise the restriction of energy-dense foods and provide advice with regard to appropriate food types, as well as to provide some general guidance concerning increased physical activity. For those unable to lose weight, a more prescriptive approach based on calorie-counting as well as an exercise prescription may be helpful, especially when this approach is used in conjunction with behavioral modification techniques.

The role of liquid or solid packaged meal replacements intended to be used instead of one or two regular meals per day can facilitate substantial energy reduction. However their place, as well as the role of very low calorie diets (VLCDs), which provide 800 or fewer calories daily in the management of obesity in diabetes, remains to be established. There is no doubt that they can be associated with rapid and substantial weight loss with impressive improvement in glycemic control. The long-term benefits are less clear since weight regain frequently occurs when normal meals are reintroduced. There is some evidence that despite greater initial weight loss, when VLCDs are used for induction of weight loss, a conventional program is associated with greater sustained reduction in weight and improvement in several clinical and metabolic measures. When VLCDs are used, such as in the management of severe obesity, this should be under the supervision of experienced physicians and dietitians or nutritionists since major alterations in hypoglycemic therapy may be needed and care taken to ensure an adequate intake of essential nutrients. Long-term dietary support, including behavioral modification techniques are essential [6]. Use of existing weight loss drugs has little or no place in the management of overweight and obesity in diabetes. Appropriately selected patients typically have impressive reductions in body weight and dramatic improvements in glycemic control and some cardiovascular risk factors following bariatric surgery.

For those with T2DM who are not overweight, and for the majority of those with T1DM, self-selected energy intakes are appropriate. It is important to ensure that energy intake is sufficient to achieve growth and development in childhood and adolescence. The prescription of insulin in excess of requirements may lead to weight gain. Overweight patients with T1DM can often appreciably improve glycemic control and at the same time reduce insulin requirements if they are able to lose weight. With increasing rates of obesity in North America and most European countries it is hardly surprising that an increasing number of people with T1DM are also presenting with overweight and obesity and associated insulin resistance. It is important that this situation be recognized and managed with advice to lose weight.

Quantity and nature of dietary fat

The recommendations on dietary fat intake are based on epidemiologic studies in nondiabetic subjects and those with diabetes and controlled dietary intervention studies involving glycemic control and cardiovascular disease risk factors as surrogate endpoints. Most risk factors for cardiovascular disease first identified in nondiabetic subjects also operate in people with diabetes. The striking relationship between saturated and *trans* unsaturated fatty acids and coronary heart disease [7] and the adverse effect of these fatty acids on the atherogenic low-density lipoproteins and lipoprotein [6,8] and insulin sensitivity provide convincing evidence for the recommendations to appreciably reduce their intakes. Saturated fatty acids may also induce a detrimental postprandial lipid profile compared with monounsaturated fat in nondiabetic and diabetic subjects [9] and have the potential to increase postprandial insulinemia in obese subjects with T2DM [10]. Exchange of saturated fatty acids with unsaturated fatty acids improves insulin sensitivity [8]. The European recommendations suggest a reduction in saturated and *trans* unsaturated fatty acids to below 10% TE, or to less than 8% if LDL-cholesterol is elevated. The ADA recommendations suggest that all people with diabetes should reduce their intake of saturated fat to below 7% and that intake of *trans* fat should be minimized. This represents appreciable reductions, given that intakes are currently up to twice this level in North America and Europe [11]. Based on research in nondiabetic individuals, it appears that myristic and palmitic acids have the greatest adverse effect on LDL-cholesterol and stearic acid has little or no effect. Lauric acid has an intermediate effect [12].

Partial substitution of *n*-6 polyunsaturated fatty acids (chiefly linoleic acid) for saturated fatty acids may help to reduce LDL-cholesterol and has been associated with reduced risk of coronary heart disease events [13] but in large quantities (i.e., more than 10% of TE) may reduce HDL and increase lipid peroxidation. *n*-3 Polyunsaturated fatty acids (eicosapentaenoic and docosahexaenoic acids), chiefly derived from oily fish, can help to reduce triglycerides and VLDL, as well as reduce the risk of thrombosis as a result of reduced platelet aggregation. However, these fatty acids have a variable effect on LDL and the most appropriate ratio of *n*-3 to *n*-6 unsaturated fatty acids has yet to be established. Total intake of polyunsaturated fatty acids is very low in most European countries and North America and some increase may be appropriate, though total intake should not exceed 10% of TE. Fish oil supplements are not advised for routine use although increased intake of fish will facilitate the reduction of saturated fat as well as increase the intake of naturally occurring *n*-3 fatty acids, especially if oily fish is eaten regularly. Both the ADA and European recommendations include advice to consume 2–3 servings of fish each week and the European recommendations also encourage consumption of plant sources of *n*-3 fatty acids (e.g. rapeseed oil, soyabean oil, nuts, and some green leafy vegetables).

Monounsaturated fatty acids with a *cis* configuration (principally oleic acid from olive oil and the rapeseed oil derivative, canola) on the other hand, appear not only to facilitate the reduction of saturated fatty acids (SAFA), but may be associated with an overall more favorable lipid profile when compared with carbohydrate-rich food used as replacement for saturated fats [14]. There is also some evidence that blood pressure levels may be reduced and peripheral insulin sensitivity improved on diets relatively high in monounsaturated fatty acids. A fairly wide range of intakes (10–20% TE) is considered acceptable resulting in an appreciably wider acceptable range of intakes for total fat than was permitted in previous recommendations. However, given the contribution of fat regardless of its nature to the overall energy density of the diet, it is recommended that total fat intake should not exceed 35% TE or 30% TE for those who are overweight. The degree of adiposity, metabolic characteristics and personal and cultural preferences all contribute to the decision as to the optimal quantity and nature of total fat. It has been suggested that monounsaturated fatty acids may be more appropriate sources of replacement energy for saturated fatty acids than carbohydrates, given that high intakes of some carbohydrate-rich foods may result in increased levels of triglycerides and reduced HDL. Such advice needs to take into account the high energy density of all fats and the potential of fiber-rich carbohydrate foods to promote satiety. This is further discussed in a later section of the chapter.

Substantial reduction of saturated fat will almost invariably be associated with a reduction of dietary cholesterol, to 200 mg or less per day, the intake suggested in the ADA recommendations. There is no good evidence to suggest that a further reduction of dietary cholesterol confers additional benefit when intake of saturated fat is already low.

Protein

Protein intake in Europe and North America ranges between 10% and 20% TE which corresponds to $1.3–2.0\,g\,kg^{-1}$ body weight. This exceeds requirements. In T1DM albumin excretion rate increases with protein intake beyond this level especially in the presence of poor glycemic control and/or hypertension. The recommended range of intake in patients with no evidence of nephropathy is 10–20% TE in Europe and 15–20% TE in the United States. In patients with T1DM and established nephropathy there is evidence that limiting protein intake to the lower end of the recommended range of intakes ($0.8\,g\,kg^{-1}$ body weight per day) improves outcome measured as reaching end-stage renal disease or death [15]. Thus in this group of patients, this level of restriction is recommended. For patients with T1DM and incipient nephropathy (microalbuminuria) and those with T2DM and established or incipient nephropathy, there is insufficient evidence to make firm recommendations regarding protein restriction. There is also insufficient evidence to make recommendations about preferred protein type.

Recently published evidence and the availability of several popular diet books have led to the suggestion that high protein diets (20–30% TE) which may also be high in fat and relatively low in carbohydrate are particularly helpful in facilitating weight reduction and improving the metabolic derangements associated with insulin resistance, notably high triglyceride and low HDL-cholesterol levels [16]. The only long-term study in people with T2DM which attempted to implement a diet with dietary protein in this range found that the majority of patients did not comply with the high protein advice over an 18-month period [17]. In that study a modest improvement in glycemic control occurred in both the high protein and the relatively high carbohydrate control diet and was associated with similar modest weight loss which occurred on both diets. While it seems reasonable, especially for overweight or obese patients with T2DM, to suggest protein intakes at the upper end of the recommended range (i.e., 20%TE), in order to facilitate reduction of rapidly digested carbohydrate (see section that follows) higher intakes are not currently advised. Long-term effects of high protein diets in diabetes are not known.

Carbohydrate, dietary fiber, and glycemic index

Traditionally in many affluent societies, low carbohydrate diets (40% or less TE) were recommended for people with diabetes. This was inevitably associated with an increase in dietary fat, especially saturated fat. With increasing evidence for the

deleterious effects of saturated fatty acids and the potential for dietary fiber, especially soluble gel-forming fiber, to improve glycemic control and some cardiovascular risk factors, there was a trend towards recommending much higher intakes of carbohydrate, up to 60% TE [18]. What was frequently not appreciated was that the benefits of a high carbohydrate, high fiber diet had been demonstrated in studies involving very high intakes of fiber-rich carbohydrate (40 g dietary fiber or more per day) typically derived from intact fruit and vegetables, legumes, and lightly processed wholegrain cereals [19]. This advice regarding the acceptability of high carbohydrate intakes was frequently translated, by patients and sometimes health professionals, into diets high in rapidly digested starchy foods such as rice, potato, and "wholemeal" bread. There was no evidence that such foods conferred benefit in terms of glycemic control. Indeed it is unsurprising that a meta-analysis comparing the effect of high carbohydrate diets (49–60% carbohydrate, 20–32% fat, 7–13% MUFA) with diets higher in monounsaturated fat and lower in carbohydrate (36–40% carbohydrate, 37–50% fat, 22–33% monounsaturated fatty acids (MUFA) found that triglyceride levels were appreciably lower on the high MUFA diets. Fasting glucose levels were slightly lower and HDL-cholesterol levels slightly higher on the high MUFA diets than the high carbohydrate diets which were typically rich in starchy foods [20]. Thus the current European recommendations specify a wide range of acceptable intakes for total carbohydrate (45–60% TE) which is based on the limits for total fat and protein intakes. They specify that metabolic characteristics suggest the most appropriate intake within this range. For those with marked insulin resistance and appreciably raised triglyceride levels, intakes towards the lower end of the range are preferred.

Source of dietary carbohydrate is particularly important. Both European and US recommendations encourage a dietary pattern that includes carbohydrate from a range of fruits, vegetables, and wholegrains with particular emphasis on legumes which are rich in soluble fiber. For those who choose an intake at the upper end of the recommended range, it is particularly important to emphasize foods rich in dietary fiber. Dietary fiber is emphasized in both sets of recommendations with the European set suggesting 20 g/1000 kcal or more if possible, about half of which should be soluble. Daily consumption of at least five servings of fiber-rich vegetables or fruit, and at least four servings per week of legumes help to provide minimum requirements and cereal-based foods should, whenever possible, be wholegrain and high in fiber.

Low carbohydrate diets in which carbohydrate is restricted to below $130\,g\,d^{-1}$ are not recommended, both because such diets are likely to be unacceptably high in fat and because carbohydrate-containing foods are important sources of vitamins and minerals.

Postprandial glycemia is influenced by amount and type of carbohydrate. Carbohydrate counting is a helpful approach for patients with T1DM and those with T2DM who are treated with insulin, to determine insulin dose required to cover a carbohydrate-containing meal or snack [21]. However, nature of carbohydrate is also a determinant of glucose levels after a meal. The glycemic index (GI), (defined as the incremental blood glucose area following ingestion of 25–50 g available carbohydrates expressed as a percentage of the corresponding area following ingestion of carbohydrate from a reference food, glucose, or white bread) of carbohydrate-containing foods provides an indication of the extent of expected glucose rise following their consumption [22]. This in turn depends upon the speed, extent, and site of digestion and absorption. Examples of the GI values of some carbohydrate-containing foods is shown in Table 40.2. Rapidly digested starchy foods and some sugars tend to have high glycemic indices though sucrose, high fructose corn syrups (HFCS), and foods rich in both do not, because fructose (sucrose contains 50% fructose and HFCS, 55% fructose) is very rapidly metabolized and does not influence blood glucose levels. While the GI of carbohydrate-containing foods does provide some indication as to their glycemic potential, and there is some evidence that emphasis on low GI foods can improve overall glycemic control, [23] the index does have a number of important limitations [24]. These include the appreciable inter-and intra-individual variation and the fact that the index provides no indication as to the overall impact of the food. For example, energy-dense foods high in fat and sugar such as ice-cream tend to have a low glycemic index. However, when considering similar products such as bread, the choice of a low GI brand may be helpful, especially when the choice is made also taking into account other attributes such as fiber and sodium content. As a general rule, the index should not be used for foods such as ice-cream which are also high in fat. Sucrose and other free sugars may be incorporated into the diet provided contribution to TE is taken into account and intake does not exceed $50\,g\,d^{-1}$.

Dietary fiber supplements are not generally recommended.

Distribution of energy from macronutrients

The major dietary restriction is that of saturated and *trans* unsaturated fatty acids to no more than 10% of TE, or 7% if LDL-cholesterol is raised according to the European recommendations. The ADA recommendations suggest that all people with diabetes should derive less than 7% TE for saturated and *trans* fatty acids should be restricted. If energy restriction is not required (i.e., if BMI is in the satisfactory range) the lost energy may be replaced by either an increase in *cis* monounsaturated fatty acids from vegetable sources (e.g. olive oil, canola) or carbohydrates. Both these nutrients have a wide acceptable range of intakes: *cis* monounsaturated fatty acid, 10–20% of TE, total carbohydrates, 45–60% of TE. This involves a restriction of fatty meat and meat products as well as high-fat dairy products, confectionery, cakes, and high-fat manufactured foods, which

are replaced by monounsaturated vegetable oils and spreads and fiber-rich or carbohydrates. It is with regard to nature of carbohydrate that there has been an apparent discrepancy between North American and European recommendations. Early versions of the ADA recommendations, while acknowledging the health benefits of "foods containing carbohydrate from wholegrains, fruit, vegetables and low-fat milk," suggested that the total amount of carbohydrate was more important than source and type, that sucrose did not increase glycemia to a greater extent than isocaloric amounts of starch and that restriction by people with diabetes was therefore unnecessary. European recommendations are much more directional and stated clearly that vegetables, legumes, fruits, and cereal-derived foods were the preferred carbohydrate choices and that wherever possible, they should have a low glycemic index and be high in dietary fiber. The more recent ADA guidelines are now more specific in terms of glycemic index and dietary fiber so the discrepancies between the two sets of recommendations are much less marked. In most European countries and North America, intake of *n*-3 and *n*-6 polyunsaturated fatty acids is relatively low and some increase up to a maximum of 10% TE may be appropriate. It is important to emphasize that the overall distribution of macronutrients is no different from that widely advised for the population as a whole in countries with high coronary heart disease (CHD) risk. For those who are overweight it is appropriate to recommend only partial replacement of energy lost by reduced intake of saturated and *trans* unsaturated fatty acids. A number of overweight patients have opted to try very low carbohydrate, high fat or high protein dietary approaches to weight loss (e.g. the Atkins Diet, Zone diet). While such diets often achieve short-term weight loss and associated benefits, including dose reduction of hypoglycemic drug therapy, extreme dietary practices should be discouraged at least until such a time as they have been subjected to further appropriate evaluation. At present there is no evidence that in the long term they are more efficacious than established dietary approaches, and there is at least a theoretical basis for believing that there may be some deleterious long-term effects. Protein intakes at the upper end of the recommended range (20% TE) and carbohydrate at the lower end (45% TE) are acceptable and may be particularly appropriate for overweight patients and those with features of the metabolic syndrome.

It should be clear from this discussion that the acceptable range of intakes of macronutrients is compatible with the wide range of dietary patterns traditionally consumed by people throughout Europe and North America. The Mediterranean diet typically eaten in southern Europe is very different from that consumed in the Nordic countries, yet both these dietary patterns, as well as the "typical" British diet consisting of meat and three vegetables at main meals, can all be prepared so that macronutrient distribution conforms with the recommended ranges. This applies also to the wide variety of Asian cuisines which are now popular in Europe and North America. However, it should be noted that while using traditional methods

of preparation many dishes are indeed suitable for people with diabetes, but when traditional recipes have been adapted for Western consumption they may have increased amounts of fats, sugars, and rapidly digested starches.

Antioxidant nutrients, vitamins, and minerals

A whole range of micronutrients have at one time or another been the focus of attention in diabetes. Dietary sodium restriction can produce substantial reduction in blood pressure in mildly hypertensive patients with T2DM [25] and to enhance the blood pressure lowering effects of other dietary manipulations (low-fat dairy products, fruits, and vegetables) in nondiabetic individuals [26]. So all people with diabetes are advised to restrict salt intake to under $6\,g\,d^{-1}$. Those with elevated blood pressure may be recommended to further reduce their intake.

There is a substantial body of evidence from prospective studies in nondiabetic individuals which suggests that a range of antioxidant nutrients and good food sources of these (fruits, vegetables, nuts, berries) are protective against cardiovascular disease [27,28]. People with diabetes may be in a state of increased oxidative stress. There is some evidence from short-term studies that consumption of foods rich in these nutrients and supplementation with a range of synthetic micronutrients that some markers of oxidative stress can be favorably influenced by substantial intakes [29]. However, there is no convincing evidence from studies with clinical endpoints and even some evidence for potential harm with high doses of antioxidant supplements. Thus it seems appropriate to recommend foods rich in dietary antioxidants, but supplements are not recommended.

There has also been interest in possible roles for chromium, potassium, magnesium and zinc, deficiencies of which may aggravate carbohydrate intolerance. Deficiencies, especially of magnesium, have been detected in poorly controlled type 1 patients. There is no convincing evidence for supplementation with these or any other minerals, vitamins or trace elements unless deficiency has been established.

Alcohol

The same caution regarding alcohol intake that applies to the general population applies to those with diabetes. Alcohol consumption should be eliminated as far as possible in those with a history of pancreatitis, hypertriglyceridemia, those who are overweight, and those with hypertension. When alcohol is taken by those on insulin or tablets, it should be taken with meals because of its potentially profound hypoglycemic effect, which can be prolonged or delayed. There is evidence, principally in people who do not have diabetes, that a modest intake of alcohol may reduce cardiovascular risk because of a beneficial effect on HDL-cholesterol, reduced coagulability,

and reduced lipid oxidation [30,31]. However, this evidence is not considered sufficient to justify a recommendation to drink alcohol if individuals are not already doing so. For those who choose to drink alcoholic beverages and do not have the complications listed above, a quantity equivalent to $10\,g\,d^{-1}$ for women and $20\,g\,d^{-1}$ for men is acceptable.

Sweeteners, supplements and functional foods

A range of nonnutritive sweeteners is available for use in drinks, cooking, and manufactured foods. Aspartame is generally included in this category although it is a dipeptide, because it is so sweet that only very small quantities are required. These sweeteners provide a useful means of reducing energy intake.

Several nutritive sweeteners, notably fructose and sorbitol have also been used extensively for home use and manufactured foods in so-called "diabetic foods" as an alternative to sucrose. They are not associated with postprandial glycemia but have the same (fructose) or half (sorbitol) the energy content as sucrose and may be associated with untoward effects. For example in large quantities fructose may cause diarrhea and hypertriglyceridemia. However, while they have no proven advantage over sucrose, moderate intakes (up to a maximum of $50\,g\,d^{-1}$) do not appear to have adverse gastrointestinal or metabolic effects.

Many functional foods and supplements are promoted as beneficial for the management of people with diabetes or reducing the risk of complications. Some have been shown to have potentially relevant functional effects but have not been tested in long-term clinical trials. Most are expensive and many are relatively high in energy. While sugar-free and low-calorie products may be useful for many people with diabetes, functional foods and supplements are not generally recommended in "official" recommendations for people with diabetes. It is generally accepted that the principal benefits of nutritional approaches to the treatment (and prevention) of diabetes are derived from the appropriate intakes of usual foods.

Implementation of diet therapy

The dietary prescription for people with diabetes often involves a major change in lifestyle and physicians are rarely competent to be the sole providers of appropriate advice, though their support in emphasizing the importance of nutrition therapy is critical in encouraging compliance with the advice given by dietitians and appropriately trained nutritionists. Behavioral techniques are almost always needed in addition to the practical advice regarding food purchase and preparation required to translate nutrition principles into practice. Implementation of current nutrition therapy should be easier than in the past since the principles of diet composition are those recommended for

Table 40.3 Guidelines for optimal food choices

Eat regularly (servings to aim for/serving size)	Eat in moderate amounts		Seldom or avoid
	More often	Occasionally	
Pulses & legumes (2–3 per week/1 cup cooked) Beans (e.g. haricot, red kidney, soya, baked, black-eyed) Lentils Chick-peas, split peas	Peanuts (unsalted) (see under nuts below) Falafel baked or "dry fried" Low-fat refried beans	Refried beans cooked in a little suitable MUFA or PUFA oil Falafel baked or fried in a little suitable MUFA or PUFA oil	Deep-fried legumes
Fruit—with skin where possible (2–4 per day/1 piece) raw	Fruit stewed without sugar or canned in water or fruit juice (as part of fruit recommendation) ($1/_2$ to $2/_3$ cup)	Dried fruit Fruit juice (diluted)	Fruit canned in heavy syrup Fruit leather Crystallized fruit Fruit juice (undiluted)
Vegetables Colored vegetables (3–5 per day/$1/_2$ to 1 cup) Fresh or frozen, cooked (e.g. carrots, cauliflower, cabbage, spinach, green beans, peas, corn, beetroot, zucchini) Salad or raw vegetables (e.g. tomato, lettuce, cucumber, radish, celery, capsicum)		*Starchy vegetables* In total servings 2–3/week (serving size: 1 small/$1/_2$ cup) Potatoes (with skin) Sweet potatoes (baked) Pumpkin baked Parsnip baked Once a fortnight or less: Thick-cut wedges baked without fat or sprayed with a little mono- or polyunsaturated oil	Mashed or instant potatoes Crisps, potato cakes, potato scallops, baked chips, thin potato wedges; Thick-cut chips or roast vegetables cooked in a little mono- or polyunsaturated oil Hot chips or French fries Vegetables cooked in dripping, lard, or hardened coconut fat, or hard margarine or frequently reheated oil
Breads and cereals At least $1/_2$–$2/_3$ wholegrain Breads & rolls (1 slice/1 small roll); Cereals ($1/_3$–1 cup) Oats, barley Wholegrain breads and rolls Pumpernickel bread Low-fat wholemeal crispbreads Wholegrain cereals Unsweetened breakfast cereals (e.g. All Bran™, Weetbix™, Weetabix™, wholegrain porridge, Bircher muesli—made with rolled oats low-fat yoghurt & low-fat milk, grated apple (a little dried fruit & nuts—optional), oat-based unsweetened muesli) Brown rice, wholegrain rice Doongara, Basmati rice Wholemeal pasta, wholemeal flour, rye flour	Jasmine rice Oatcakes	White bread, white flour Unsweetened breakfast cereals (e.g. Special K™, Cornflakes™)	Sugar-coated cereals (e.g. Sugar Puffs™, Frosties™, Coco Pops™) Pudding cereals (e.g. rice, sago, custard powder) White flour, white pasta

Meat, poultry, and fish Meat & poultry (3–4 per week/50–120 g cooked weight)	Lean meat or poultry, cooked by low-fat cooking methods (baked, microwaved, grilled)	Lean meat or poultry, roasted or cooked in a little MUFA or PUFA oil	Meat fat, poultry fat or skin, fried meat, duck, goose, meat pies, fatty mince, hot dogs, sausages Luncheon meat, salami, canned corned beef, fatty bacon, crackling
Fish (1–2 per week/100–200 g cooked weight) White fish Some oily fish (50–75 g) (e.g. salmon, tuna, sardines tinned in water)	Shellfish or other seafood cooked without fat (poached, baked, microwaved, grilled, steamed)	Fish, shellfish or other seafood cooked in a little MUFA or PUFA oil	Deep-fried fish, or seafood Fish & meat paté
Eggs (1 egg or egg white) Egg whites	Whole eggs (up to 3 per week) As desired in savory dishes		
Dairy products—low fat (LF) (2–3 per day/100–150 mL) LF/low-sugar yoghurt Skimmed milk Cottage cheese (40 g) Curd cheese (serving size 20 g) Low-fat quark	Homemade fruit smoothies made with skimmed milk Semi-hard cheese, mozzarella, gouda, edam, brie, feta, (serving size 30 g)	Plain ice-cream, full-fat sweetened yoghurt, whole milk, flavored milk Reduced fat cream Hard cheese e.g. cheddar, Tasty, blue cheese (serving size 20 g) Double-cream brie and camembert Lite cream cheese Lite sour cream	Full fat and extra high fat specialty creams and yoghurts Specialty ice-creams Cream cheese Cheese spreads Condensed milk Sour cream Milk-shakes with sugar syrup flavoring
Fats and oils (1–2 tsp)	Use in place of spreads high in animal fats: cis monounsaturated oils (e.g. olive or canola) cis polyunsaturated oils (e.g. sunflower, soya, grapeseed) Soft margarine 1 tsp Margarine/butter mixture 1 tsp	Butter $\frac{1}{2}$–1 tsp Peanut butter 1–$1\frac{1}{2}$ tsp (no added sugar or salt) 1 tablespoon pesto 1 tablespoon olives	Lard, suet, dripping Oils: coconut, palm Partially hydrogenated oils hydrogenated fats (e.g. hard margarines)
Nuts and seeds Nuts	Use in place of foods high in animal fats (3–5 per week/20–30 g), (e.g. almonds, pistachios, Brazil nuts, hazelnuts, cashews, macadamias, peanuts, pine nuts, walnuts, pecans (nuts should be unsalted, and not roasted in other oils or fats)	Lightly salted nuts	Heavily salted nuts and /or nuts roasted in unknown fats
	Use in place of foods high in animal fats Nut butters (no added sugar or salt) 1–$1\frac{1}{2}$ tsp		
Seeds	1 tbsp (e.g. sunflower, sesame, pumpkin, flaxseed) Avocado 1 tbsp		

Table 40.3 (*continued*)

Eat regularly (servings to aim for/serving size)	More often	Eat in moderate amounts	
		Occasionally	Seldom or avoid
Made-up dishes Home-made vegetable or clear soups	"Cream" soups made with skim milk Sauces made with skim milk and wholemeal flour	Filo pastry a little suitable MUFA or PUFA oil (between several sheets not each sheet) Pastry made with wholemeal flour and MUFA or PUFA oils or soft margarines Low-fat, low-sugar, high-fiber desserts, cakes, or biscuits made from special recipes, with wholemeal flour and soft MUFA or PUFA margarine	Cream soups, sauces with cream Flaky or short pastry Meat or pork pies Sausage rolls Sweet pastries High-fat, high-sugar desserts
Takeaways	Wholemeal, wholegrain rolls or wraps or bread with very lean meat or poultry or vegetarian fillings and assorted salad fillings	Pasta (small serving with tomatoes, chicken, lean meat, seafood or pesto) Steamed rice or noodles, plus chicken, fish or beef with vegetables Chicken or meat cooked in a sauce without butter or cream Burger grilled meat patty and salad Grilled chicken or meat with salad Oven-baked chips, wedges Pizza (small) with tomato, vegetable, lean meat, chicken or fish, very little cheese	Deep-fried takeaways Pasta with cream sauce Cream or butter sauces Thin crisps Salami Extra cheese
Spreads and preserves	Marmite™, Promite™	Jam, marmalade	Sugar, glucose, honey, syrup, treacle, Sweets, chocolates, fudges, butterscotch Fruit mincemeat Lemon curd Sweet sauces & toppings
Drinks Water, tea, coffee, tomato juice, sugar-free drinks (e.g. soda water, sugar-free squash)		Spirits with diet mixers, dry wine, & sherry French champagne Low-calorie beer	Sweet wines, liqueurs Sweet sherry, sweetened fruit drink. Sweetened fizzy drinks High-fat drinks with alcohol & cream Pre-mixed drinks Regular beers

healthy eating and the foods required by those with diabetes should not differ appreciably from those appropriate for the entire family.

Most individuals with T1DM will be using rapid-acting insulin as a component of a basal-bolus insulin regime or via an insulin pump. For them, the total carbohydrate content of meals and snacks, typically estimated by carbohydrate counting or experience-based estimation, together with pre-meal blood glucose level will guide the dose of the insulin bolus [21, 32]. This method enables a more flexible approach than the earlier system of prescribing a fixed number of carbohydrate exchanges to match prescribed insulin dose. For those on fixed insulin regimens total carbohydrate will need to be kept fairly consistent with regard to time and amount on a day-to-day basis in order to achieve satisfactory glycemic control.

Some people with T2DM on intensive insulin regimes will also require advice with regard to timing and amount of total carbohydrate. However, for the majority, emphasis will be on dietary modifications that ensure appropriate energy intakes, reductions of saturated and *trans* fatty acids and sodium and adequate intake of other nutrients. While individualized specialist dietary advice from dietitians, taking into account individual preferences and metabolic characteristics, is obviously desirable for all people with diabetes, this will not be universally available. Many people with T2DM may be able to cope adequately with generalized advice about nutritional and dietary principles (Table 40.3) provided they receive the support of other available health professionals (e.g. specialist diabetes nurses or trained community workers) and family members. Regular follow-up by nonspecialist nurses can also encourage dietary compliance and has been shown to support maintenance of weight loss over a prolonged period [33].

While the role of physical activity in the prevention and treatment of diabetes has received considerable attention [34] the early ACTID randomized control has shown that the addition of an activity intervention conferred no additional benefit to that observed in the group that received only intensive dietary advice [35].

[2] Department of Nutrition, Exercise and Sports, University of Copenhagen, Copenhagen, Denmark

Key points

- Exercise represents a challenge to diabetes regulation, particularly in type 1 diabetes.

- Based on experience and frequent blood glucose measurements, the insulin dosage must be adjusted to intensity and duration of exercise and food intake.

- The diabetes patient in good metabolic control should reduce the insulin dosage prior to exercise, more so the higher the energy expenditure during exercise.

- In youth prone to spontaneous exercise, carbohydrate administration may be a more feasible means of preventing hypoglycemia than adjustment of insulin dosage.

- Paying due respect to possible long-term complications, with proper education and medical control and guidance diabetes patients can participate in all kinds of sports, even at world-class levels.

- In type 2 diabetes, but not in type 1, a reduction in HbA1c can be expected with regular exercise.

- Regular exercise reduces the risk of cardiovascular morbidity and increases life expectancy in diabetes.

- Exercise reduces the risk of gestational diabetes and is also recommended for individuals with this condition.

- Physical activity reduces the risk of getting type 2 diabetes, especially in people at increased risk.

Introduction

A certain minimum of skeletal muscle activity in excess of that required for basal pulmonary ventilation is necessary for all people, including diabetic patients, for everyday activities such as dressing, cooking, and eating. House work and walking and bicycling for the purpose of transportation represent heavier exercise, and intense physical activity may be required for occupational activities in agriculture, forestry, fishing, industry and, obviously, professional sports and ballet. In addition to such obligatory exercise, many people also engage in sports to increase their physical, psychological, and social well-being.

However, the trend is that the advance of modern technology promotes physical inactivity. This is unfortunate, because physical activity has a pivotal role in health promotion and prevention of disease, including type 2 diabetes (T2DM) [1,2]. For that reason it has become necessary for national health authorities to recommend planned, regular exercise [3]. The recommendation also applies to diabetic patients. Among the weighty arguments are that evidence exists for both type 1 and type 2 diabetics that exercise reduces the risk of cardiovascular events [4,5] and increases life expectancy [6–8]. The recommendation for patients with diabetes to take physical activity is supported by both national academic, diabetes and sports associations, for example the American Diabetes Association and the American College of Sports Medicine [9].

Because exercise is an essential part of life and, furthermore, is associated with potential health benefits, it is important to be aware of the inherent risks and to know how it influences the body with regard to organ function, dietary needs, and interaction with medicine and the environment. This is of particular interest in people with diabetes since many of the characteristics and manifestations of this disease would be expected to interfere with work performance and vice versa.

Exercise physiology

In healthy humans who perform severe dynamic exercise with big muscle groups, oxygen uptake may increase 15–20-fold due to increased metabolic rate in the working muscles. In these, arterioles dilate, capillaries are recruited and fluid accumulates intra- and extracellularly. Pulmonary ventilation may exceed 100 L per min and cardiac output increases to 20–30 L per min to meet the needs of the working muscles, while blood flow to resting muscles, the splanchnic area, and the kidneys decreases.

Systolic and mean arterial blood pressure increase. Some of the produced heat is accumulated in the body, and the core temperature may exceed 40°C. Most of the heat is removed by evaporation, however, and the sweat rate during exercise in hot and humid air may be 2 liters per hour. The glomerular filtration rate decreases while potassium is released from contracting muscle and may attain a concentration in plasma of $8\,mEq\,L^{-1}$ at maximum exercise.

During exercise in the postabsorptive state the energy demand of the working muscles is met by breakdown of intramuscular glycogen and triglyceride stores as well as by an increased supply of glucose from the liver and free fatty acids (FFA) from extramuscular triglyceride stores [10]. Protein oxidation does not increase significantly unless muscle glycogen stores are exhausted. The relative contribution of carbohydrate to overall energy delivery increases with exercise intensity, while fat oxidation in absolute terms peaks at 70% of V_{O2max} and becomes negligible at maximum exercise. Breakdown of intramuscular energy stores as well as overall carbohydrate oxidation wanes with time during mild to moderate exercise. The increase in glucose production in response to exercise primarily reflects hepatic glycogenolysis but contribution from gluconeogenesis increases with duration of mild exercise. At moderate workloads the plasma glucose concentration is usually well maintained (Figure 41.1). However, at high work intensities the glucose concentration increases [10,11],
Figure 41.1 Simplified schemes of substrate fluxes and their hormonal regulation in healthy subjects in the postabsorptive state at rest (upper panel) and during moderate exercise (lower panel). FFA means free fatty acids; "+" and "-" indicate enhancing and inhibiting effects, respectively. During exercise a decrease in plasma insulin and an increase in concentrations of counterregulatory hormones are seen, while plasma glucose remains constant, because an increase in glucose uptake in contracting muscles is matched by an increase in hepatic glucose output.

while hypoglycemia may develop during prolonged exercise [12], these deviations being favored when prior to exercise carbohydrate stores are high and low, respectively [13,14]. Because selection of fuel for oxidation is affected by substrate availability [10,15], exogenous nutrients, particularly glucose, influence muscle metabolism when administered before or during exercise [16–18].

Hormonal regulation

The autonomic neuroendocrine system serves the coordination of the various functions of the body to allow coping with the physical challenges of life. Accordingly, it follows from the depicted multiple perturbations that depending on its intensity and duration, exercise may elicit extensive autonomic endocrine responses. These adaptations resemble those seen in hypoglycemia, early fasting, hyperthermia, surgery, and hemorrhage, that is, they include a decrease in plasma insulin as well as an increase in sympathetic nervous activity, insulin counterregulatory hormones, and hormones retaining sodium and water in the kidneys [15].

The endocrine adaptations to exercise are based on the same fundamental regulatory principles that are thought to control circulatory, respiratory, and thermoregulatory responses in exercise, a fact guaranteeing that the responses of the major physiologic systems are highly coordinated [15]. At the onset of exercise, nervous impulses from motor centers in the brain and from working muscles elicit an increase in sympatho-adrenal activity and in the release of some pituitary hormones (e.g. GH, ACTH, β-endorphin, prolactin, and ADH). This exercise-specific, "feedforward" stimulus is determined by workload relative to the individual's maximum capacity (V_{O2}/V_{O2max}) rather than by absolute workload. The primary neuroendocrine responses, in turn, change the secretion of subordinate endocrine cells, for example sympathetic nervous activity depresses insulin secretion by α-receptor-mediated mechanisms, while the renin-angiotensin-ADH system is stimulated by β-receptor mechanisms, and ACTH stimulates cortisol secretion.

The fast nervous mechanisms intimately related to contractile activity operate throughout exercise, but the hormonal responses may be gradually intensified according to feedback from metabolic error signals (among which a decrease in glucose availability is the most important) as well as from nonmetabolic error signals sensed by blood pressure and volume, osmolality, electrolyte and temperature receptors. At high work rates, feedforward control dominates. At low exercise intensities, just as at rest, feedback regulation dominates the hormonal changes, and at least in humans, an increase in plasma glucagon concentration is always predominantly determined by a decrease in plasma glucose availability. The primary setting of the hormonal response to exercise depends on the state of the organism with respect to training, nutrition, hydration, phase of menstrual cycle, and state of health [15].

Hormonal influence on exercise metabolism

The overall hormonal response to exercise appears to be geared to stimulation of catabolic processes resulting in lipolysis and glycogenolysis in adipose tissue, muscle, and liver. With regard to hepatic glucose production during exercise, the regulation particularly in humans is not clear [15]. A decrease in plasma insulin concentration is always essential, because glucose production during exercise varies inversely with modest artificial changes in insulin levels [15]. In rats and dogs the exercise-induced increases in glucagon and epinephrine concentrations are the major determinants of the increase in glucose production [10,15]. Furthermore, the potency of the rise in glucagon has been shown to be enhanced by the accompanying fall in insulin [19]. On the other hand, both in these species, and in guinea pigs [20] and humans [21,22] sympathetic liver nerves do not influence glucose production in exercise. Strangely, neither epinephrine [22,23] nor glucagon [10,22] or angiotensin [24] seem to be major stimuli in humans. In healthy man, arterial glucagon does not increase above basal levels until after more than 1 hour of submaximal exercise, and it even decreases during maximal exercise, when glucose production peaks [10].

It may seem surprising that during exercise the glucose uptake in muscle varies inversely with the rate of secretion and the plasma concentration of insulin [10]. However, muscle contractions per se enhance muscle glucose uptake by mechanisms that are independent of insulin [25,26]. These mechanisms include feedforward components, which are probably Ca^{++} mediated [27,28], as well as feedback components, which may be mediated by AMPK [29–31]. Recently the involvement of the small cytoskeleton-regulating GTPase Rac1 has also been demonstrated [32]. In isolated skeletal muscle, contractions are a more powerful stimulus to glucose transport than insulin, and the two stimuli are fully additive [33]. They translocate glucose transporting protein (GLUT4) to the sarcolemma by at least partly differing signaling mechanisms and have different preferences for recruitment from the various intracellular GLUT4 stores [34].

During exercise the decrease in plasma insulin curbs the increase in glucose uptake in muscle, and the same is true for the increase in plasma epinephrine [23]. The effect is due to the direct actions of hormonal changes on glucose transport as well as to the inhibition of glucose uptake secondary to an enhancement of lipolysis and muscle glycogen breakdown [10,35,36]. In addition to the decrease in plasma insulin, both sympathetic nerve activity and epinephrine are major determinants of adipose tissue lipolysis in exercise [37].

The primary setting of substrate mobilization in exercise is simple. The same enzymes, that is, glycogen phosphorylase and hormone-sensitive lipase (HSL) and adipose tissue triglyceride lipase (ATGL), are flux generating for glycogenolysis and lipolysis, respectively, in both muscle and extramuscular stores of glycogen (i.e., liver) and triglyceride (i.e., adipose

tissue). Furthermore, the enzymes are stimulated by the same neuroendocrine changes and in muscle they are also stimulated in parallel by mechanisms accompanying contractions [36,38,39]. The autonomic neuroendocrine response to exercise includes increases in several components potentially enhancing the activity of glycogen phosphorylase, HSL and ATGL, and, in addition, a decrease in insulin, a hormone inhibiting these enzymes. Metaphorically speaking, substrate mobilization in exercise is increased by stepping on the accelerator while releasing the brake (Figure 41.1).

Metabolism during exercise in diabetics

Type 1
While the insulin concentration in the plasma of healthy people is automatically adjusted to any work condition, this adjustment does not take place in type 1 diabetics. Instead they have to carry out the work during the influence of the given amount of insulin they have administered subcutaneously. Therefore, the changes in metabolism that take place in type 1 diabetics in response to exercise usually reflect either too much or too little insulin in plasma.

While in healthy people plasma insulin is low during exercise, that of diabetics is not low if they take the same dose of insulin as they use on non-exercise days. In diabetics, in contrast to healthy subjects, plasma insulin may even increase during exercise because absorption of insulin may be favored by exercise-induced movements of the site of administration in the skin and increases in skin blood flow [40,41]. A high plasma insulin level implies risk of hypoglycemia because the normal increase in hepatic glucose production is inhibited, and insulin stimulates muscular glucose uptake both directly and by an inhibition of FFA release from triglyceride stores and, in turn, of fat combustion [40] (Figure 41.2).

If, then, type 1 diabetics reduce their dose of insulin, they risk getting too little insulin in plasma [42]. In this event, hepatic glucose production and the release of FFA from adipose tissue increase more than normal, while muscular glucose uptake is inhibited (Figure 41.2). The high plasma FFA level and an increased hepatic fractional extraction and conversion to ketone bodies of FFA result in an increased production of ketone acids and increased muscular fat oxidation [43]. In patients who are insulin-deficient prior to exercise, increased fat oxidation during work reflects increased stores of intramuscular triglycerides and these stores will be depleted during exercise [44–46]. In such patients the muscular glycogen concentration and exercise-induced glycogen depletion are reduced in comparison to those of healthy subjects [45]. Nevertheless, lactate accumulation is enhanced as a consequence of incomplete carbohydrate oxidation due to increased fat oxidation and diminished pyruvate dehydrogenase activity [44,47,48]. Furthermore, an increased production of lactic acid, glycerol, and glycogenic amino acids results in higher hepatic gluconeogenesis during

exercise than in control subjects [44,47]. Taken together, in insulin-deficient exercising individuals, the plasma glucose concentration increases and acid accumulates—the diabetic state deteriorates [42,47].

It is evident that the physically active diabetic, like the sedentary one, balances between hyper- and hypoglycemia. However, exercise accelerates the rate at which both of these unpleasant alternatives develop (Figure 41.3). Exercise increases sympathetic nervous activity and the plasma concentrations of counterregulatory hormones, a phenomenon which per se causes an accumulation of glucose and lactic acid and ketone bodies in plasma by enhancing glucose and FFA production and inhibiting glucose uptake in muscle [49,50]. Moreover, in diabetics who have taken too little insulin the autonomic neuroendocrine response is exaggerated, and so are its effects. Therefore, these patients are especially prone to hyperglycemia and ketoacidosis [43,48,51–54]. The increase in plasma glucose during exercise may even in itself stimulate the counterregulatory hormonal response [54]. In other words, the type 1 diabetic who exercises with a plasma insulin concentration that is too low, in terms of fuel mobilization steps harder on the accelerator and less hard on the brake than healthy subjects do.

On the other hand, the plasma glucose concentration decreases more rapidly in diabetics, who take too much insulin, if they also exercise [55–57] (Figures 41.2 and 41.4). This phenomenon is due to the fact that glucose uptake in muscle becomes extra high because contractions per se increase glucose uptake in muscle cells and also increase the sensitivity to insulin of glucose uptake in these cells [58] and because delivery of insulin and glucose to the sarcolemma of contracting muscle cells is increased by increases in blood flow and capillary permeability surface area product in exercising muscle [59]. Furthermore, the indirect enhancing effect of insulin on glucose uptake in muscle, which is exerted via inhibition of fat cell lipolysis, may be augmented in exercise compared with rest, because insulin prevents the marked increase in lipolysis which normally occurs during exercise. In addition, insulin can prevent the rise in hepatic glucose production during exercise. Because glucose turnover is accelerated during exercise, inhibition of hepatic glucose production leads to more marked hypoglycemia than at rest when glucose turnover is less. Of note are recent studies indicating that in type 1 diabetics as well as in healthy subjects antecedent hypoglycemia or exercise blunts neuroendocrine and metabolic counterregulatory responses to subsequent hypoglycemia or exercise, and, accordingly, increase the risk of severe hypoglycemia at either stress [60].

Type 2
Type 2 diabetics, in contrast to type 1 diabetics, have some insulin secretory capacity, and their insulin secretion changes with needs in principle as it does in normal individuals. Accordingly, if they are not treated with exogenous insulin, they cannot respond as dramatically to exercise as type 1 diabetics. In other words, they do not run the same metabolic
Figure 41.2 Simplified schemes of substrate fluxes and their hormonal regulation during moderate exercise in type 1 diabetes patients, who have taken a normal dose of insulin (upper panel) or are insulin deficient (lower panel). After insulin administration the uptake of glucose in contracting muscles increases more than the hepatic glucose output, and the plasma glucose concentration falls. In contrast, without insulin the plasma glucose concentration rises, because hepatic glucose output exceeds muscle glucose uptake. The increases in counterregulatory hormones and FFA are exaggerated and the production of ketones is increased.

risks with exercise. Still, although insulin resistance is a major hallmark of T2DM contraction-mediated glucose transport in type 2 diabetic muscle is not reduced [59,61,62]. It has been claimed to rely more on NO than seen in normal muscle [63], but exercise-induced increases in atypical PKC and AMPK alpha2 activities in muscle are normal [64,65].

So, in diet-treated type 2 diabetics, who perform prolonged mild to moderate exercise in the postabsorptive state, a marked reduction in hyperglycemia can be seen [66,67]. This reflects that hyperglycemia enhances the exercise-induced increase in muscle glucose uptake and inhibits the increase in hepatic glucose production, effects which are reinforced by the fact that

the secretion and, in turn, plasma concentration of insulin, at least as long as hyperglycemia prevails, are not depressed as readily as in healthy subjects [66,68–71].

The rate of decrease in plasma glucose concentration is augmented, if sulfonylurea drugs are taken shortly before exercise (Figure 41.5) [72]. Sulfonylureas stimulate insulin secretion, and although the secretion is depressed by exercise, the plasma insulin concentration remains higher than during exercise without prior drug intake (Figure 41.5). This relative hyperinsulinemia explains that the exercise-induced rise in hepatic glucose production is lower and, accordingly, the hypoglycemic effect of exercise is larger than when exercise
Figure 41.3 An illustration of the delicate balance between too little and too much insulin available during exercise. After an overnight fast 24-year-old type 1 diabetes patients injected 4 IU of regular insulin either 3 h (white dots, $n = 11$) or 1 h (black dots, $n = 15$) before intermittent, graded, exhausting ergometer cycle exercise (5×10 min at $50–150$ W with 5-min rest intervals). The plasma glucose concentration increased 5.1 mM and decreased 4.7 mM, respectively. The broken line represents data from six healthy subjects. Source: Adapted from Zander 1983 [42]. Reproduced with permission of Thieme Publishing Group.

is performed without acute sulfonylurea intake. Interestingly, the hyperinsulinemia apparently overrides the effect of the augmented counterregulatory hormone response observed when sulfonylureas are taken (Figure 41.5) [72]. Abstaining from sulfonylurea treatment for 5 days does not result in an exaggerated counterregulatory hormone response and hyperglycemic reaction to exercise as seen in type 1 diabetics after insulin withdrawal [73]. In contrast, during 60 min of moderate exercise the plasma glucose concentration decreases more after prolonged sulfonylurea abstention than after abstention only from the morning dose prior to exercise [73]. This is because the basal plasma glucose level increases during the prolonged

drug abstention, and, in turn, maintains the basal insulin secretion and impairs the exercise-induced depression of insulin secretion. The augmented hyperglycemia and relatively high insulin levels then blunt the exercise-induced increase in hepatic glucose output, thereby promoting a decrease in plasma glucose [73]. Still, an exaggerated counterregulatory hormone response and glucose production and an ensuing increase in plasma glucose is seen in type 2 diabetics performing brief intense exercise in the postabsorptive state [74].

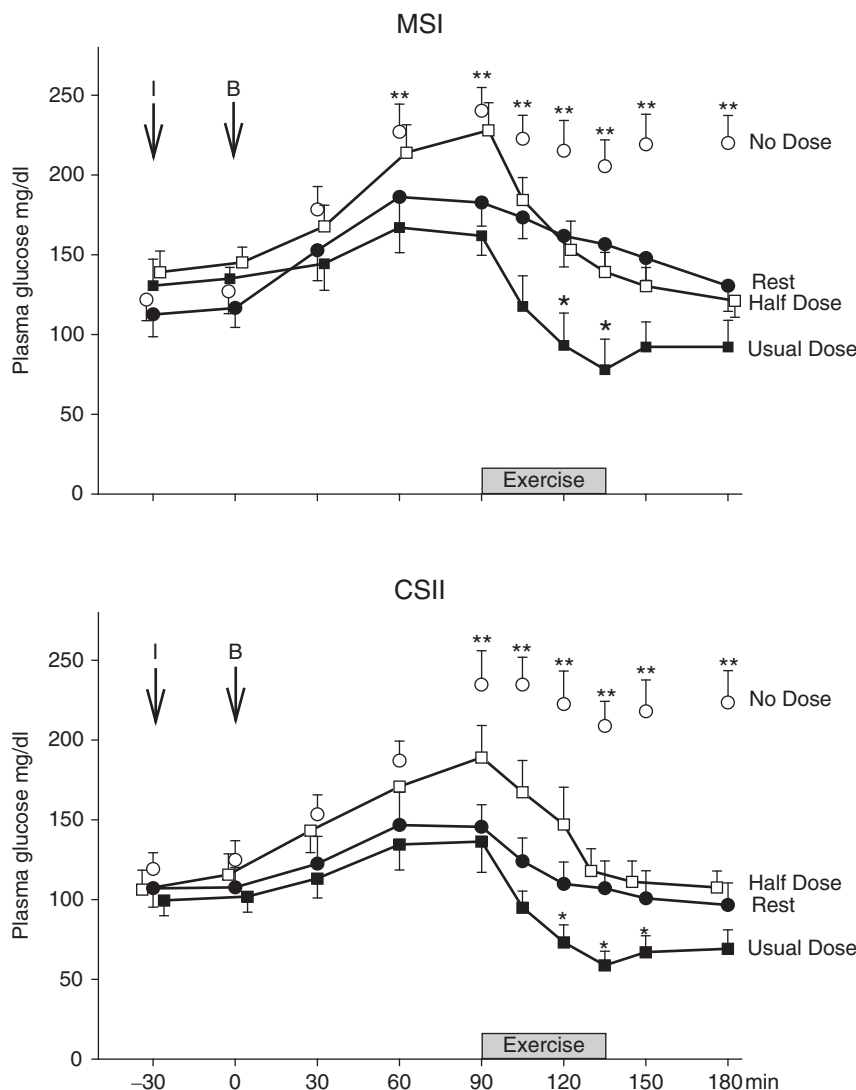
The plasma glucose concentration also decreases markedly during prolonged moderate exercise in type 2 diabetics in the postprandial state (Figure 41.6) [75]. This is accompanied by


Figure 41.4 The interaction between breakfast (B), ergometer cycle exercise (45 min at 55% V_{02max}) and different doses of insulin (I) in 15–18-year-old type 1 diabetes patients treated with multiple subcutaneous insulin injections (MSI, upper panel, $n = 6$) or continuous subcutaneous insulin infusion (CSII (pump), lower panel, $n = 7$). If premeal insulin dose is reduced plasma glucose concentration increases before exercise but during exercise hypoglycemia is avoided. The two regimens allow similar coping with exercise. $*p < 0.05$ and $**p < 0.01$ vs. rest. Source: Adapted from Schiffrin [57]. Reproduced with permission of American Diabetes Association.

reduced meal-induced increases in insulin and C-peptide concentrations and reflects an exercise-induced increase in glucose clearance, while glucose appearance in plasma is unchanged [75]. The plasma glucose lowering effect of exercise is higher after a meal than in the fasted state, even at a time at which only plasma insulin and not plasma glucose is increased in the former compared to the latter condition [76]. In contrast to findings in the postabsorptive state [74], in the postprandial state hyperglycemia is not aggravated during severe exercise [77]. This probably reflects that the counterregulatory hormonal response to exercise is lower in the latter compared with the former state, and that, furthermore, the high glucose and insulin concentrations accompanying food intake inhibit

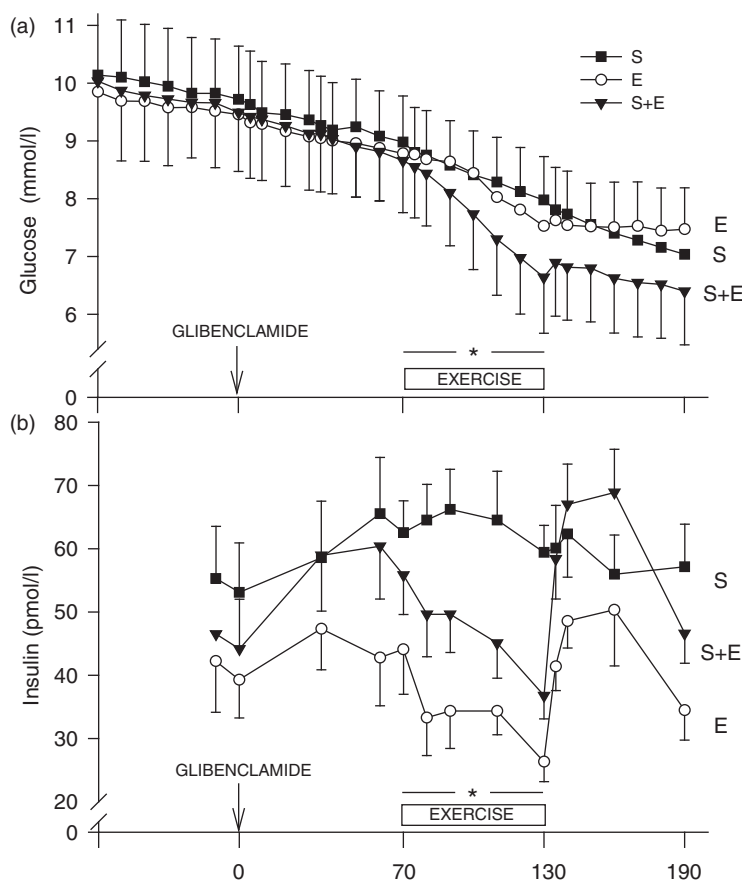
an exercise-induced increase in hepatic glucose production and enhance an increase in glucose uptake in muscle [77]. Repeated, high intensity exercise in fact reduces both glucose concentrations and insulin secretion after a meal [77]. Interestingly, exercise-induced reductions in glucose, insulin, and C-peptide responses are similar during repeated, high intensity exercise compared with isocaloric but prolonged moderate postprandial exercise [77]. This indicates that in the postprandial state overall energy expenditure is the major determinant of exercise-induced changes in overall glucose homeostasis and insulin secretion in type 2 diabetic patients. The peak exercise intensity is not of major importance in this respect. Apparently, in terms of reducing glucose levels and insulin


Figure 41.5 The interaction between sulfonylurea (S, 7 mg glibenclamide) and exercise (E, 60 min of ergometer cycle exercise at 57% V_{O2max}) on plasma glucose and insulin concentrations in eight postabsorptive type 2 diabetic patients. *indicates that average concentrations from 70 to 130 min differed ($p < 0.05$) between the three experiments. Source: Adapted from Larsen 1999 [72].

secretion following a meal, acute exercise has little effect beyond that of increasing energy expenditure. In line with this view, it has been shown that a reduction of energy content of a meal has the same lowering effect on postprandial glycemia and insulin secretion as an equivalent exercise-induced increase in energy expenditure (Figure 41.6) [75]. Neither prolonged moderate nor intermittent severe exercise performed in the postprandial state influence glucose and insulin responses to a subsequent meal [75,77]. Besides postprandial hyperglycemia, the exaggerated meal-induced increases in chylomicron and very low-density lipoprotein triglyceride concentrations are also reduced by postprandial prolonged exercise in type 2 diabetics [78].

Special patient groups
Children
V_{02max} and physical work capacity are impaired in young people with T1DM [79]. Inactivity likely contributes to lower fitness and performance because when matched for age, body size, and physical activity, adolescents with T1DM have similar cardiac function and V_{02max} to healthy adolescents [79]. Children often engage in spontaneous exercise the extent of which is generally unpredictable, a fact which makes appropriate adjustments in

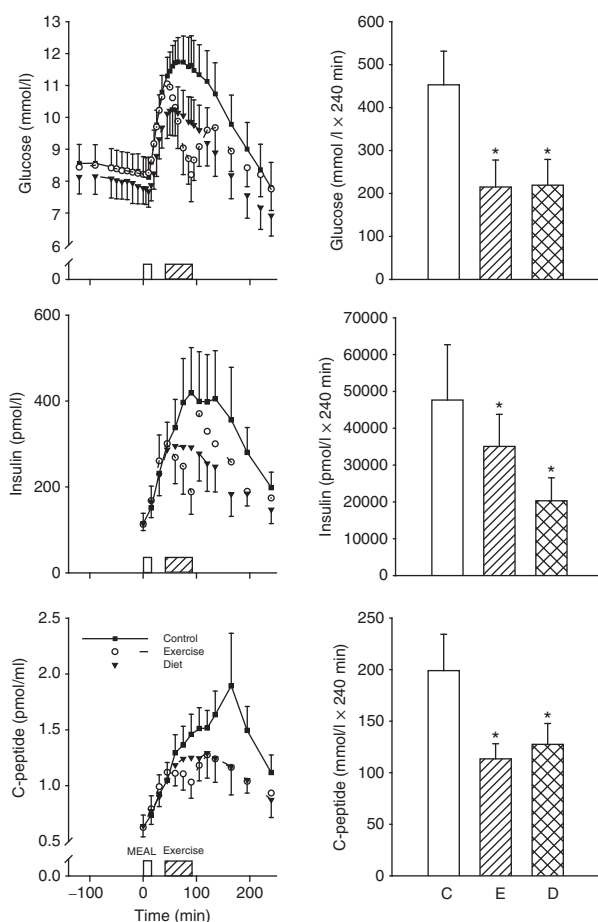
insulin and diet difficult. Such adjustments are also rendered difficult by the fact that during similar conditions the variation in glycemic response to exercise is high in children both on the inter- and intra-individual level [80]. Furthermore, glycemic awareness seems to be poor in adolescents with T1DM [81], and their perceived exertion is high compared to findings in control subjects [82], while carbohydrate utilization may be impaired [83]. Hypoglycemia during prolonged moderate postprandial exercise is a particular threat due to prevailing hyperinsulinemia, but intermittent ingestion of carbohydrate beverages matched with total carbohydrate utilization has been shown to markedly attenuate the drop in plasma glucose in exercising adolescents with T1DM [84]. The fact that severe postexercise late-onset hypoglycemia may be particularly prevalent in active diabetic children probably reflects that proper strategies are not adopted to replace muscle and liver glycogen stores [85]. If, on the other hand, brief high intensity exercise is performed, a dramatic increase in plasma glucose along with marked increases in catecholamine concentrations may be seen even in well-insulinized diabetic children [86], just as is the case in diabetic adults [87]. Because requirements for insulin and food change with growth and sexual maturation, physical


Figure 41.6 The effect of moderate exercise (45 min of ergometer cycle exercise at 53% V_{O2max}) 45 min after start of breakfast on plasma glucose, insulin, and C-peptide concentrations in nine diet-treated type 2 diabetes patients. The patients were studied at three occasions: control day without exercise (C), exercise day (E), and diet day without exercise (D). On D breakfast was reduced corresponding to the extra energy expenditure during exercise on E. Incremental areas under the plasma concentration versus time curves (AUC) calculated from 0 to 240 min are shown to the right. *indicates difference from C ($p < 0.05$). activity in youth with diabetes has to be particularly carefully managed. In the case of an amenorrheic athletic girl with T1DM, dietary instruction is paramount as part of the exercise program, not only as treatment of the exercise-induced menstrual disorder, but also to maintain as near-normal plasma glucose levels as is safe and feasible, because chronic hyperglycemia delays puberty and is associated with short stature [88]. Today almost 50% of children and adolescents under the age of 18 with diabetes have T2DM, and 80% of these are overweight [89]. These facts call for attention with regard to physical activity in the prevention and treatment of T2DM in children [89].

Pregnant women

Oligo- or amenorrhea may in both healthy and diabetic women result from excessive physical training [15]. If these women

want to become pregnant they must reduce or abstain from exercise. Even in normally menstruating insulin-treated women this step may be necessary to achieve a glucoregulation compatible with fertilization, because exercise adds an additional variable that may make glucose control difficult [88]. For the same reason it has been concluded that the utility of an exercise program as part of the glucose control program for pregnant woman with pregestational diabetes, be it type 1 or type 2, is questionable [88]. The paramount management goal for the best outcome of pregnancy is to achieve and maintain normoglycemia. However, exercise-induced deterioration may only be associated with a risk of spontaneous abortion if plasma glucose levels exceed 4 standard deviations of the mean level of a healthy pregnant woman [88].

Insulin sensitivity declines progressively during the second half of gestation, and if insulin secretion is not increased appropriately, the previously nondiabetic pregnant woman develops gestational diabetes. However, physical activity before and during pregnancy reduces the risk of both gestational diabetes and pre-eclampsia [90]. Exercise of moderate intensity is recommended along with diet in the treatment of patients with gestational diabetes, because exercise may lower plasma glucose levels and insulin needs [91–93] and reduces weight gain [94] in the patients.

After menopause basal metabolic rate decreases. Exercise may help postmenopausal women with T2DM to avoid weight gain [88]. If postmenopausal women with diabetes undertake hormonal replacement therapy with estrogen and progesterone their insulin requirement increases. When an exercise program is combined with hormonal replacement therapy, the insulin regimen becomes especially challenging [88].

Autonomic neuropathy

Diabetic autonomic neuropathy influences cardiovascular and hormonal responses to exercise. Exercise endurance as well as V_{O2max} are diminished by autonomic neuropathy [95,96]. Vagal insufficiency results in an increased heart rate at rest, and impairment of both parasympathetic and sympathetic nervous function results in diminished increases in heart rate in response to exercise [95–98]. In patients with diabetic autonomic neuropathy stroke volume is diminished both at rest and during exercise [95]. This seems to reflect impaired cardiac contractility, which may be due to diminished cardiac adrenergic stimulation, impaired sympathetically mediated dilatation of coronary resistance vessels, and diabetic cardiomyopathy [95,99]. The mentioned changes imply that in diabetics with autonomic neuropathy cardiac output increases less with exercise than in diabetics without neuropathy [95]. Further, probably reflecting splanchnic sympathetic neuropathy and, in turn, reduced splanchnic vasoconstriction, the exercise-induced increase in hepatosplanchnic vascular resistance is also diminished in patients with autonomic neuropathy [95]. Defective increases in cardiac output and hepatosplanchnic resistance explain that the arterial blood pressure response to exercise

may also be reduced [95,97]. The mentioned impairments in cardiovascular function are less pronounced in patients with diminished beat to beat variation in heart rate during deep breathing than in patients, who also have orthostatic hypotension, showing that the impairments are directly related to the degree of autonomic neuropathy [95,96]. In patients with autonomic neuropathy the hypoxic ventilatory drive may be impaired [100], but nevertheless these patients may show an exaggerated pulmonary ventilation during heavy exercise [101]. Impaired sympathetic function is accompanied by diminished catecholamine responses to exercise, and responses of GH, cortisol, renin, and pancreatic polypeptide may also be diminished in diabetics with autonomic neuropathy [102–104]. However, metabolite responses may be only slightly influenced, a fact which probably reflects augmented sensitivity of target tissues to hormonal stimulation in these patients [105].

Adaptations to training

Insulin action and secretion in healthy subjects

Insulin action on whole body glucose disposal is reduced in the early recovery period after short-term maximal dynamic exercise in both trained and untrained subjects [11], and insulin action is also reduced after marathon running [106]. These findings have been ascribed to elevated levels of counterregulatory hormones as well as metabolic inhibition of glucose uptake in muscle by accumulated glycolytic intermediates and increased fat metabolism, respectively. After a marathon the reduced insulin action is accompanied by impaired muscle glycogen resynthesis in the face of unaltered GLUT4 content and increased glycogen synthase activity [106,107]. Unaccustomed, severe exercise, for example eccentric exercise, which causes muscle damage also impairs insulin action [108,109]. The reduced insulin action after eccentric exercise includes diminished insulin action on glucose uptake and glycogen synthesis in the recruited muscles and is seen in the face of diminished total GLUT4 content [110], decreased insulin signaling [111] but unaltered glycogen synthase activity [108,109]. In accordance with these findings insulin-mediated glucose transport has been shown to be decreased in rat muscle after eccentric contractions, while glycogen synthase responded normally [112].

However, nonexhausting endurance-type exercise that consists predominantly of concentric contractions enhances the effect of insulin on glucose disposal [113–115], and insulin action increases over the full range of activity levels from inactivity during bedrest to daily endurance training [109,116]. Also regular strength training enhances insulin action [109]. The exercise-induced increase in insulin effect is predominantly located in the recruited muscles and reflects local contraction-dependent mechanisms [109,115]. The enhancing effect of acute exercise to a large extent reflects muscle glycogen depletion and accompanying glycogen synthase activation and includes an increase in insulin sensitivity of muscle glucose transport [109,113,117]. With increasing habitual physical activity level the muscle GLUT4 content increases and so does insulin responsiveness of glucose transport [109]. Also muscle capillarization increases, and these changes may to some extent reflect conversion of muscle fibers from type II B/X to type II A and perhaps further on to type I [109]. The muscle content of key enzymes in glucose storage and metabolism also increases with level of physical activity [109,118]. The mentioned changes explain that muscle glucose extraction during insulin stimulation varies directly with activity level [109]. Because the ability of insulin to stimulate muscle blood flow also increases with activity level, insulin-mediated glucose uptake in muscle must vary directly with level of habitual activity [109]. After acute exercise glucose taken up in muscle is predominantly subjected to storage as glycogen while glycolysis is diminished [109]. In contrast, in the trained as well as in the inactive state insulin-mediated glycogen storage and glycolysis essentially vary in parallel [59,109].

Exercise may also enhance insulin action in extramuscular tissues. The hepatic glucose storage capacity is increased by training [109]. Furthermore, in trained subjects the suppressive effect of insulin on hepatic glucose production is increased probably reflecting an effect of the last exercise bout [109,118]. The suppressive action of insulin on pancreatic secretion of insulin and glucagon may also be enhanced by exercise making it difficult to tell whether exercise-induced changes in hepatic sensitivity to insulin are direct or secondary to changes in glucagon secretion [109]. In line with the view that the insulin sparing effect of training is more pronounced in peripheral tissues than in liver, studies carried out during ordinary living conditions have shown that a relatively smaller fraction of secreted insulin is delivered to "posthepatic" tissues in athletes compared to healthy subjects [109]. This finding also points at a higher hepatic insulin extraction after training [109]. Microdialysis studies have shown that training enhances insulin-mediated glucose uptake in human subcutaneous adipose tissue [119], and studies in rats have shown a similar effect in several intra-abdominal adipose tissues [120]. In line with these findings, in adipocytes, insulin-mediated glucose transport as well as GLUT4 mRNA and protein are increased by training [109]. While such effects are not elicited by a single bout of exercise, insulin-mediated suppression of lipolysis is enhanced by both acute exercise and training [109,119]. Training decreases basal concentrations in plasma of triglyceride, total cholesterol and LDL cholesterol, and increases the HDL fraction of total cholesterol [121]. Postprandial lipidemia is also reduced by both acute exercise and training. The effect of training probably reflects increased lipoprotein lipase activity in muscle [109,122]. In addition to enhancing the effect of insulin on carbohydrate and fat metabolism, physical activity also enhances the protein anabolic effect of insulin in human muscle [109,123,124].

The insulin secretory capacity is not changed by a single bout of dynamic exercise [109], but otherwise an inverse relationship between glucose-stimulated pancreatic β-cell secretion and insulin sensitivity is seen over the whole range of physical activity levels from inactivity during bedrest to elite training [109]. The training-induced decrease in insulin secretion capacity reflects adaptations within the β-cells including increased glucose metabolism [109], but the mechanism for the development of the adaptations is not known. The training-induced reduction in insulin and C-peptide responses may be more pronounced during oral compared with intravenous glucose testing, a fact which may be due to diminished glucose-induced incretin secretion from the gut after exercise and training [109]. Comparison between trained, detrained, and untrained subjects has revealed that the training-induced decrease in β-cell secretory capacity may very accurately match the accompanying increase in insulin action, because during hyperglycemic clamping glucose disposal was identical in the groups despite widely differing plasma insulin concentrations [109]. However, upon extreme athletic training oral glucose tolerance is better than in untrained subjects indicating that enhancement of insulin action is not fully compensated by reduced β-cell function [109]. In athletes the sparing of insulin secretion and reduction in plasma glucose concentration are only relative to food intake; over a 24-hour period trained subjects have, compared with untrained subjects, the same overall insulin secretion and average plasma glucose concentration in the face of a higher food intake, and they also have similar blood HbA1c concentrations [109]. Accordingly, the predominant health benefit of the adaptations in pancreas and insulin-sensitive tissues resulting from intense training is that the adaptations allow the necessary increase in food intake without potentially harmful hyperglycemia and overloading of β cells. To this may be added lowering of arterial insulin concentrations in consequence of the training-induced increase in hepatic insulin extraction [109]. At the other end of the activity spectrum insulin secretion and action, respectively, are also not well matched. Thus, during bedrest glucose tolerance deteriorates and glucose disposal is diminished in the face of augmented insulinemia during hyperglycemic clamping illustrating that reduction in insulin sensitivity is not fully overcome by enhancement of glucose-stimulated insulin secretion [109]. This indicates that a minimal level of physical activity is necessary for normal glucose homeostasis. In this context it should be noted that adaptations in insulin secretion and action develop rapidly upon an increase in habitual physical activity but the adaptations disappear within less than 2 weeks, if the altered lifestyle is not upheld [109,125]. The described relationships between physical activity and secretion and action of insulin also apply to the elderly [109,125,126]. Of note is the fact that the tendency for plasma insulin concentrations to increase with aging can be neutralized by a physically active lifestyle [125].

Adaptations to training in diabetics
Type 1
If type 1 diabetics have a normal activity level and do not have long-term complications they also have a normal oxidative capacity of skeletal muscle and normal physical work capacity [121]. However, their skeletal muscles are insulin resistant [121]. These patients generally respond to both endurance and strength training just as healthy subjects, for example by diminished heart rate and blood pressure during rest and exercise, and increased muscle force, respectively [40,121,127]. Insulin sensitivity increases and the activity of oxidative enzymes, glycogen synthase, and hexokinase increases in muscle [40,79,121,128]. Also muscle capillarization increases but the increase may be less pronounced than in healthy subjects [40,121]. A case report indicates that improvement in insulin sensitivity through physical training may help to induce and prolong remission at onset of T1DM [129]. However, after the honeymoon period a decrease in insulin requirements with training is not a universal finding, possibly because carbohydrate intake may increase [40,121]. Since exercise makes diabetes more difficult to control, the daily fluctuations in blood glucose may increase, and the average plasma glucose concentration, which is reflected in the HbA1c level, does not generally decline during training [40,79,121]. An improved glucoregulation is more likely to occur if patients have been poorly controlled prior to training [121], probably because training is then accompanied by more attention to disease control [79]. However, type 1 diabetic patients who participate in competitive sports may even experience deterioration of glycemic control in spite of improvements in fitness [130]. This probably reflects an irregular schedule, high exercise intensities, and measures to avoid hypoglycemia in response to exercise, that is, excessive reductions in insulin dose and excessive intake of carbohydrate. Additionally, these patients may not show increased insulin sensitivity [130]. Probably reflecting the variation seen in effect of training on metabolic homeostasis some studies have found changes in plasma triglyceride and cholesterol levels upon training similar to those seen in healthy subjects, whereas other studies have not [40,121].

Type 2
Patients with T2DM have a low V_{O2max}, a low maximal peripheral O_2 extraction, and a reduced fraction of oxidative, highly insulin-responsive muscle fibers compared with healthy subjects even when matched for levels of ambient activity [118,131–133]. In agreement with this, their nonobese, nondiabetic first-degree relatives also have a low level of fitness and a high content of nonoxidative fibers in skeletal muscle [109,134]. The diminished V_{O2max} in type 2 diabetics may be explained by myocardial dysfunction and by impaired oxygen extraction due to mitochondrial dysfunction and impaired increase in capillary surface area in working muscle [73]. The myocardial phosphocreatine (PCr)/ATP ratio may be diminished in resting

diabetics, while during exercise an attenuated increase in blood flow [73] is accompanied by a faster decrease in PCr and pH in skeletal muscle [135].

In type 2 diabetics V_{O2max} as well as the enzymatic potential for oxidation and fat combustion in muscle increase normally during endurance training [40,121,136,137], whereas the increase in capillarization in muscle is impeded [40,121]. Bedrest exacerbates the insulin resistance of obese individuals with pre-existing impaired glucose tolerance [118]. Conversely, in the postabsorptive state a single bout of prolonged sub-maximal dynamic [138] or resistance [139] exercise improves whole-body insulin sensitivity in type 2 diabetics. The effect of dynamic exercise has been shown to be located both in liver and peripheral tissues [138,140]. Impairment of the activity of atypical protein kinase C in muscle is probably important for the reduced insulin-mediated glucose transport in T2DM, and this activity is increased by exercise [64]. In contrast to the reaction to submaximal exercise, in response to brief intense dynamic exercise insulin sensitivity is reduced for the first 1–2 hours postexercise but increased after 24 hours [74]. Also in the postprandial state moderate exercise seems to increase insulin-mediated glucose disposal in the immediate postexercise period, but the effect does not persist during or after the next meal [75].

Regularly repeated exercise may increase insulin sensitivity in both elderly glucose intolerant subjects [126], women with gestational diabetes [92], and type 2 diabetic patients [136,141] and their first-degree relatives [109,134] more than can be inferred from a single bout of exercise. However, the improvement may

in type 2 diabetics be difficult to detect on the whole-body level [118,142]. Studies in which type 2 diabetic patients had catheterization of leg vessels before and after bicycle training have shown that the effect of training is predominantly, but not entirely, due to an enhanced insulin-mediated glucose clearance in skeletal muscle (Figure 41.7) [136]. Possibly, an increase in the activity of the transcriptional co-activator PGC-1α and accompanying amelioration of mitochondrial dysfunction and, in turn improved oxidative metabolism, at least in part account for enhanced insulin action in muscle [143,144]. In terms of insulin signaling, it has recently been shown that the TBC1 domain family of GTPases are important regulators of GLUT4 translocation [145] and endurance training has been shown to be able to restore impaired site-specific phosphorylation of TBC1 domain family, member 4 (TBC1D4) in skeletal muscle of T2DM patients along with improvement in insulin sensitivity [146]. Insulin-mediated increase in blood flow and glucose extraction in muscle are augmented following training [134,136]. The increase in extraction is in line with a training-induced increase in muscle GLUT4 protein and mRNA [147]. The increase in glucose clearance reflects increases in both nonoxidative glycolysis and glucose storage and parts of the insulin signaling pathway [136,146]. Increases in fractional velocity of glycogen synthase and mRNA for this enzyme have been found after endurance training in diabetic muscle but total glycogen synthase, hexokinase, and lactate dehydrogenase activities were unaltered [136]. Interestingly, in T2DM patients this type of training may increase muscle glucose clearance to values seen in healthy untrained control
Figure 41.7 Insulin-mediated glucose clearance rates in trained and untrained legs in healthy young (23 yr, $n = 7$) or elderly (59 yr, $n = 8$) subjects and in type 2 diabetic patients (58 yr, $n = 7$). All subjects endurance trained one leg 30 min per day, 6 days per week for 10 weeks. Insulin was infused and glucose always clamped at the individual pretraining fasting concentration. Trained legs were studied 16 h after last exercise bout, at which time a preceding single exercise bout would have no effect in untrained legs. During insulin infusion glucose clearance was always higher in trained compared with untrained legs ($p < 0.05$) and always higher in control subjects compared with diabetics ($p < 0.05$). Source: Adapted from Dela 1999 [109].

subjects (Figure 41.7). It is of note, however, that training does not exactly revert the muscle defect in T2DM, because training, at least partly exerts its effect by enhancing blood flow and GLUT4 concentrations, variables that are not subnormal in the untrained state. Furthermore, the improvement in insulin action on skeletal muscle are in type 2 diabetics lost within a week if training is discontinued [136].

Strength training has also been shown to increase insulin action on glucose clearance in skeletal muscle of T2DM patients [148,149]. The effect was independent of changes in muscle mass and reflected an enhanced insulin-mediated increase in muscle blood flow as well as increases in protein content of the insulin receptor, GLUT4, protein kinase B α/β (Akt 1/2) and glycogen synthase.

In addition to the described effects that may be seen in weight-stable patients [136], training may increase diet-induced weight loss, and this occurrence may, in itself, increase insulin sensitivity [109,150]. Regular exercise causes a loss of intra-abdominal adipose tissue, and this correlates with improvement in insulin action [141]. However, training per se may not generally result in lower body mass, a fact which may be explained by either changes in opposite directions of lean and fat body masses, respectively, or by reduced physical activity between training periods, or by increased food intake [151].

A training-induced reduction in glucose-stimulated β-cell secretion as seen in healthy subjects would appear less expedient in T2DM patients. However, some studies have, in fact, indicated improvement in β-cell function by training in these patients [40,109]. In a study using stimulation with hyperglycemic clamping and arginine bolus, increases in β-cell responses were seen in patients, who prior to training had a moderate residual β-cell function, whereas no change was seen in patients with a low remaining secretory capacity [109]. One possible explanation could be that a diminished glucose stress resulting from an increase in target tissue insulin sensitivity may improve the secretory capacity of overloaded, yet recoverable, β cells. However, in the mentioned hyperglycemic clamp study no change in insulin sensitivity and HbA1c was seen. Interestingly, in agreement with the findings in humans, training has been shown to improve glucose-stimulated insulin secretion in rats made mildly or moderately diabetic by partial pancreatectomy, but training did not influence secretion in more severely diabetic rats [152]. Also in that study other mechanisms than reduced glycemia apparently accounted for the positive β-cell adaptation to training [152].

The impact of the training-induced adaptations in both secretion and effect of insulin on glucose homeostasis during ordinary living conditions has been evaluated in a study in which type 2 diabetic patients had blood samples drawn around the clock. Areas under plasma concentration versus time curves were identical for glucose while energy intake was at least as high when compared to before training [109]. Integrated insulin and C-peptide levels were reduced after training indicating that during physiologic conditions insulin action is enhanced

and insulin secretion spared by training [109]. The lack of change in integrated glucose levels is in accordance with the fact that a significant change in HbA1c concentration is often not seen in training studies. However, meta-analyses have revealed that training may reduce HbA1c by 0.66% [151], and that exercise intensity is a better predictor of improvement in HbA1c than exercise volume is [137]. The improvement of glucose homeostasis by regular exercise may be more marked in younger patients with T2DM and in patients with short duration of disease [109].

A single bout of prolonged dynamic exercise reduces post-prandial chylomicron triglyceridemia in type 2 diabetics. Furthermore, regular exercise has been shown to reduce fasting triglyceride concentrations in these patients, whereas total cholesterol and its subfractions are not consistently changed [40,131,142,153,154].

Benefits, risks, and precautions associated with exercise in diabetes

Benefits
In T2DM training may improve overall glycemic control. In a meta-analysis of training effects a mean fall in HbA1c concentration of 0.66% was found and such an effect should be sufficient to markedly reduce the risk of diabetic complications and death [151,155,156]. Traditionally, endurance exercise has been recommended for patients with T2DM but recently it has been shown that a combination of endurance and strength training improves the metabolic outcome as evaluated by HbA1c levels [157]. The underlying mechanism is a training-induced increase in insulin sensitivity which is accompanied by beneficial relief of overloaded β cells and diminished plasma insulin levels. Adding to the risk reduction, training also tends to favorably influence body fat [158], arterial blood pressure [159,160], baroreflex sensitivity [161], endothelium-dependent vasodilation in both conduit and resistance vessels [134,162], skin blood flow [163], the heart rate × blood pressure product at rest and during exercise [158], hypertriglyceridemia and fibrinolysis [159,160,164], and has antioxidant and anti-inflammatory effects [165]. In line with these findings, cohort studies have in fact shown that in type 2 diabetic patients cardiovascular morbidity and mortality vary inversely with both physical fitness and level of physical activity and may be 50% lower in physically active compared with sedentary individuals [4,6,166].

In type 1 diabetics, exercise renders metabolic regulation difficult, and improvement of glycemic control should not be the aim of training [167]. However, endurance training in patients with T1DM has been shown to improve vascular endothelial function [168]. Furthermore, both epidemiologic prospective and retrospective studies indicate that regular physical activity in type 1 diabetics does protect against macrovascular as well as microvascular complications and increases life expectancy [5,7,168]. In both types of diabetes, additional proven benefits of regular physical activity are maintenance or improvement of

aerobic exercise capacity and muscle strength and, accordingly, a better tolerance towards physical demands. Another benefit that has been shown in healthy subjects and which in all probability also applies to diabetics is protection against osteoporosis. Furthermore, it is a general experience that exercise and sports in diabetics like in healthy subjects may improve mental health (e.g. reducing depression and anxiety, and enhancing well-being and self-esteem) and may promote social interaction and joy in a recreational environment [79,169].

Metabolic risks and precautions

In T1DM patients the immediate risk inherent in exercise is development of hyperglycemia and ketosis or hypoglycemia, respectively, during exercise. Both conditions will extend into the post-exercise period. Hypoglycemia may even develop many hours after exercise, because enhancement of insulin sensitivity and replenishment of glycogen stores from plasma glucose may last more than 12 hours [170,171]. This means that particular caution has to be exerted when exercise is carried out in the evening. To meet these challenges the diabetic has to be in good metabolic control prior to exercise [121,131]. Furthermore, the patient must imitate the normal response to exercise by reducing the insulin dose and/or increasing carbohydrate intake (Tables 41.1 and 41.2). The necessary adjustments depend on the exercise taken, the environment, and the individual, and, accordingly, have to be individually tailored based on frequent blood glucose measurements before, during, and after exercise. Extensive exercise should not be carried out earlier than 1–2 hours after a main meal and accompanying insulin administration. The short-acting monomeric insulin analogues are absorbed faster than regular insulin and, accordingly, the risk of undesirable interaction between peak insulin concentrations and exercise is over sooner after a meal if analogues are used compared with regular insulin [172,173]. The optimum insulin dosage depends on the intensity and duration of exercise and the more energy is spent the less insulin is needed [149]. In response to short-term strenuous exercise, transient hyperglycemia may develop in well controlled type 1 diabetic patients [87]. If the diabetic is not aware of the passing nature of the hyperglycemia, the patient may be tempted to inject extra insulin and may, in turn, provoke hypoglycemia [174]. For a given amount of work

Table 41.1 General advice to the physically active insulin-dependent diabetes patient

- Be educated in exercise physiology and diabetes
- Use frequent insulin injections or pump therapy
- Reduce insulin dose prior to significant exercise
- Monitor blood glucose
- Take extra carbohydrate before, during, or after exercise
- Always carry readily digested carbohydrate
- Have regular medical examinations
- Follow good exercise practice (e.g. regarding equipment, warm-up, technique, and hydration)
- Avoid extreme conditions or exercise with a healthy person

more insulin may be needed in the morning than in the evening, perhaps due to the higher plasma cortisol concentration in the morning. If the ambient temperature is high less insulin should be injected prior to exercise because absorption from the skin may be facilitated [174]. Neither in this nor in other situations can exercise-induced hypoglycemia be avoided by changing the insulin injection site [174].

Reductions in short-acting insulin dosage taken before exercise may amount to 30–80%, and postexercise reductions may also be necessary, for example to avoid nocturnal hypoglycemia [174,175]. Similarly, in order to perform long-term physical activity, patients treated with pump therapy may have to reduce the premeal insulin bolus by more than 50% and even to stop the basal infusion rate while exercising and to reduce it 25% for several hours afterwards [176,177]. On the other hand, a necessary reduction in insulin dosage prior to less extensive exercise may result in a greater increase in plasma glucose concentrations when a meal is taken after exercise than on non-exercise days when the full insulin dose is administered [40]. Accordingly, supplemental short-acting insulin may be required, particularly if food intake is increased after exercise. If plasma glucose is below 5.5 mM before physical activity, extra carbohydrate, for example a snack, should be eaten [121,131]. It is also recommended that during exercise sessions of moderate intensity lasting more than 30 min, 15–25 g extra readily absorbable carbohydrate should be taken by adult diabetics every 30 min [18]. Carbohydrate may be supplemented by 100 mL 5–8% sucrose solution every 10 min, whereby exercise-induced fluid losses are also substituted. After prolonged exhaustive exercise 100–200 g additional carbohydrate may be needed to optimize glycogen repletion and prevent late hypoglycemia [121,178]. Prevention of hypoglycemia by carbohydrate administration before, during, and after exercise may be more realistic, particularly in youth, than adjustment of insulin dose, because activities may be spontaneous and of unforeseeable intensity and duration [79]. The total amount of carbohydrate ingested should match the carbohydrate expenditure [84], and tables exist with estimates of carbohydrate utilization during various activities in children of various body masses [79]. However, it is of note that people with T1DM tend to overeat with exercise [178].

As in T1DM patients, exercise should also be avoided in T2DM patients if metabolic control is poor [121]. However, alarming exercise-induced hyperglycemia and ketosis has not been observed in T2DM patients, and neither has exercise-induced hypoglycemia in diabetics solely treated by diet [174]. If T2DM patients are treated with insulin they should take the same precautions as T1DM patients. Although frank hypoglycemia is rare, in patients treated with oral hypoglycemic agents, antidiabetic medication, extent of exercise, and food intake should, in principle, also be mutually adjusted [72]. This means that on exercise days the dosage of the drug may have to be reduced. Because weight loss usually is desirable in these patients carbohydrate supplement is less expedient.

Table 41.2 General guidelines for regulation of insulin-dependent diabetes in relation to exercise. Exact prescriptions cannot be given due to variation depending on the individual, the physical activity, and the environment

Glucose	Measure blood glucose before, during, and after exercise.
	If blood glucose is higher than 14 mM (250 mg/100 mL) measure ketones in urine and do not exercise in case of ketonuria.
	If blood glucose is higher than 16.5 mM (300 mg/100 mL) before exercise, be cautious even if no ketosis is present.
	If blood glucose is below 5.5 mM (100 mg/100 mL) ingest extra carbohydrate, e.g. 20 g, before exercise.
	Learn the glycemic response to various activity conditions.
	Remember that hypoglycemia may develop after exercise, e.g. during the night following evening exercise.
Insulin	Reduce dose of short-acting (maybe also of intermediate- or long-acting) insulin before exercise.
	After exercise supplemental insulin may be necessary, e.g. if meals are increased. However, after extensive exercise insulin dose may have to be reduced.
Diet	Do not exercise until 1–2 h after a main meal.
	Take 15–25 g extra carbohydrate per 30 min exercise before unplanned postprandial exercise, when it is too late to reduce insulin.
	Always carry readily digestible carbohydrate in case of hypoglycemia.

Long-term complications

In both T1 and T2DM patients the presence of long-term complications is of special concern. If the patient has coronary artery disease he or she should, just as any nondiabetic patient, have an echocardiographic examination and a supervised graded exercise test with electrocardiographic and blood pressure monitoring (Table 41.3). During the test the threshold for possible development of ischemia, arrhythmia, left ventricular failure or anginal equivalents (e.g. nausea, profound dyspnea, or undue fatigue) is defined [179,180]. Exercise programs at intensities below the critical threshold can then be prescribed. For example, in patients with angina, aerobic training should be carried out at a heart rate at least 10 beats per min lower than the ischemic threshold. The patient will then benefit with gradually increasing functional capacity. Cardiac disease may also be present in patients with diabetes in the absence of coronary artery disease. Even in the absence of clinical signs of cardiac impairment, left ventricular function may be impaired during exercise in both type 1 and type 2 diabetics by mechanisms that are not well understood [179,181]. On the other hand, the increase in arterial blood pressure in response to exercise may be exaggerated in diabetics [179,182] and, in particular, in hypertensive diabetics [183]. So, in hypertensive diabetics the blood pressure response to exercise should be monitored initially, and adjustments in therapy should be made accordingly. For hypertensive diabetics as well as for diabetics with stable coronary artery disease dynamic aerobic activity of 50–75% V_{O2max} is recommended, whereas high intensity activities known to elicit high increases in blood pressure, for example heavy resistance exercises involving breath-holding, should be minimized [179].

Autonomic neuropathy is associated with increased mortality from myocardial infarction and sudden death, and it may be a marker for clinically unrecognized cardiac disease [179]. Thus,

Table 41.3 The American Diabetes Association's criteria for graded exercise testing with ECG and blood pressure measurement before increase in physical activity in diabetes patients

Age >35 years
Age >25 years and type 2 diabetes for more than 10 years or type 1 diabetes for more than 15 years
Any additional risk factor for or overt coronary heart disease
Peripheral arteriosclerosis
Proliferative retinopathy or nephropathy including microalbuminuria
Autonomic neuropathy

Source: Zinman 2003 [131].

silent ischemia upon exertion is more frequent in this condition because the anginal perceptual threshold may be increased in the presence of autonomic neuropathy [184,185]. Also diabetic cardiomyopathy with impaired left ventricular function at rest and during exercise is closely associated with cardiovascular autonomic neuropathy [186]. As is also prolonged QT interval in the ECG, and this predisposes to ventricular arrhythmias [187]. Because of the risk of an adverse cardiovascular event during exercise, a supervised graded exercise test is recommended prior to initiation of training programs in diabetics with autonomic neuropathy [131,187]. It should always be remembered that due to impaired heart rate response, in these patients rate of perceived exertion is a safer guide for exercise intensity than heart rate [187]. If the patients have orthostatic hypotension, which may be present in the absence of symptoms at rest, they may benefit from body stockings to increase venous return during exercise, and they will need long warm-up and cool-down periods of low-intensity exercise in relation to training sessions [179]. Another problem for patients with autonomic neuropathy may be reduced hypoglycemia awareness [187]. They may also have gastroparesis, which may delay the

intestinal absorption of ingested carbohydrate. So, more careful glucose monitoring is appropriate in relation to exercise. These patients may also have difficulties in thermoregulation and be prone to dehydration and electrolyte disturbances. For these reasons they are generally advised to avoid exercise in hot or cold environments and to be vigilant about adequate hydration [121,131,187]. Taken together, diabetics with autonomic neuropathy need extensive examination prior to embarking on an exercise program, and subsequent progression should be slow and carefully monitored.

Autonomic neuropathy may be accompanied by anhidrosis of the lower body resulting in dry, brittle skin that cracks easily. The tendency to fissures may be supported by compromised cutaneous vasomotion [187]. Also somatic neuropathy favors ulcer formation. Loss of protective sensation plays a major role allowing repeated trauma, the feet being in particular danger. However, motor neuropathy may also contribute by inducing interosseous muscle atrophy and, in turn, foot deformities [187,188]. Ulcers become easily infected due to poor antimicrobial defense mechanisms in diabetics, and their healing may also be impeded by peripheral atherosclerosis, which is frequently present in these patients. Leg muscle atrophy secondary to motor neuropathy as well as reduced proprioception and ensuing reduced reflex stabilization and coordination of movements predispose to traumatic injuries. In addition to ulceration such injuries may provoke a Charcot foot (neuroarthropathy) and, in turn, osteopenia predisposing to fractures of the small bones in the foot [187,189,190]. In order to avoid the potential, serious consequences of peripheral neuropathy, for example amputation, the diabetic patient suffering from this condition should inspect his or her feet daily for calluses, blisters, cuts, and scratches. Furthermore, the patient should maintain good foot hygiene, avoid wet feet, and use polyester or cotton socks and comfortable shoes with good pressure absorption. Repetitive weight-bearing exercises, for example prolonged walking and jogging, should be avoided, and instead swimming or bicycling — on a stationary bicycle in case of severely impaired coordination — can be recommended [131,188]. In addition to metabolic neuropathy, diabetes predisposes to nerve entrapment syndromes, for example including the medial or lateral plantar nerves or the median nerve in the carpal tunnel, and these syndromes also warrant exercise restrictions [187].

The potential acute ocular complications of exercise in diabetic retinopathy are intraretinal, preretinal, or vitrous hemorrhage from damaged retinal capillaries or fragile new vessels as well as retinal detachment due to bleeding or traction mediated by newly formed fibrous tissue [131,191]. Such events may be provoked by increases in arterial pressure in vascular beds with poor autoregulation and/or increases in venous pressure and by trauma, respectively. Furthermore, an exercise-induced increase in GH secretion has been speculated to contribute to development of diabetic retinopathy [191]. In agreement with this hypothesis, it has been found that plasma GH concentrations increase during exercise in diabetics with retinopathy but not in diabetics without retinopathy [192]. However, that difference may simply reflect that the former group was more heavily strained than the latter, because workloads were not adjusted to individual exercise capacities, which may very well have been lower in patients when compared to patients without retinopathy [193,194]. Nonetheless, the best available studies indicate that exercise of moderate activity does not worsen diabetic retinopathy [121,195,196]. In both T1 and T2DM retinopathy is associated with impaired cardiac performance and reduced exercise capacity [193,194], and also abnormal autonomic regulation of ophthalmic circulation during exercise has been described in diabetics [197]. However, studies of people with diabetic retinopathy have shown cardiovascular improvement with moderate physical training [198]. With appropriate hemodynamic and glucose monitoring, patients with diabetic retinopathy, who have regular eye examinations by a retinal specialist, can exercise safely [191]. According to a conservative estimate an acceptable maximum systolic blood pressure during exercise is 200 mmHg [191]. In case of untreated proliferative or very severe nonproliferative retinopathy severe exercise, for example including breath holding, pounding or jarring, and activities that lower the head below waist level, should be avoided [131,191]. Acceptable activities would be swimming, bicycling, and walking. Patients whose retinopathy has been adequately treated with laser therapy can probably undertake even strenuous exercise without undue risk after a period of 6 weeks.

In both type 1 and type 2 diabetics, exercise may provoke transient microalbuminuria, and if abnormal albumin excretion is present at rest exercise increases the albuminuria due to increased glomerular permeability [199,200]. Exercise-induced increases in albumin excretion correlate with exercise-induced increases in systolic blood pressure, and the latter may be exaggerated in diabetics [182,201]. The exercise-induced increase in albumin excretion can be ameliorated by both antihypertensive medical treatment and good metabolic control [200,202]. It is a matter of concern whether diabetics, who exercise regularly and thus have more exercise-induced albuminuria and blood pressure increases, run a risk of more rapid progression of nephropathy. However, comparisons between diabetics with different activity levels do not confirm this suspicion [203]. Although no permanent adverse effects have been documented, diabetics with microalbuminuria or overt albuminuria are nevertheless often dissuaded from strenuous physical activity [121,131,200]. Prior to embarking on a moderate- to high-intensity physical activity program these patients should be examined for macro- and microvascular disease including a graded exercise test with blood pressure monitoring, and those who suffer from hypertension should be well treated for this disease. In end-stage renal disease, probably reflecting chronic uremia, inactivity and accompanying autonomic neuropathy and heart disease, the aerobic exercise capacity is markedly reduced due to both reductions in oxygen carrying capacity of the blood (diminished maximal cardiac output and hemoglobin

concentration) and in oxygen extraction by muscle [204,205]. Also muscle strength is reduced [206,207]. The influence of uremia is illustrated by the fact that kidney transplantation leads to increases in hemoglobin and aerobic capacity [205]. Patients with end-stage renal disease can benefit from training, which may take place either on off-dialysis days or during hemodialysis [208]. The latter option offers a number of advantages, such as improved compliance to exercise, monitoring of potassium and glucose concentrations, and less muscle cramping and hypotensive episodes during dialysis. Patients treated by continuous ambulatory peritoneal dialysis have also been successfully trained [209]. Before initiation of an exercise program diabetics with end-stage renal disease should be screened for macro- and microvascular disease, the examination including a supervised graded exercise test [208]. Due to their susceptibility to fluid and electrolyte disturbances these patients are advised to avoid exercising in extreme environmental conditions [208].

Other conditions requiring special precautions

Type 2 diabetics are mostly overweight and, accordingly, more prone to overload injuries. Degenerative joint disease is more common in these patients. For these reasons, swimming, bicycling, rowing, and walking are preferable to pounding weight-bearing exercise such as jogging. During pregnancy the diabetic woman must abstain from more than mild exercise or even be prescribed bedrest if she develops medical complications such as hypertension or albuminuria or obstetrical complications, for example resulting in vaginal bleeding or evidence of intrauterine growth retardation [88,210]. Stroke and amputation are common disabling conditions in diabetic individuals. Rehabilitation requires therapeutic exercise, during which caution should be exerted due to the high risk of concurring diabetic long-term complications [211]. Age and duration of diabetes are independent criteria for supervised graded exercise testing of diabetics prior to training because these variables are related to the risk of unrecognized cardiovascular disease (Table 41.3) [131]. Finally, it has to be remembered that particularly older diabetics often take other drugs than insulin or oral hypoglycemic agents, and that these drugs may cause alterations in the metabolic and cardiovascular response to exercise and potentially limit physical performance [212]. For instance, β-adrenergic antagonists tend to reduce cardiac output and muscle blood flow and also promote development of hypoglycemia while masking the symptoms of this.

Guidelines for training in diabetes

For both type 1 and type 2 diabetics physical activity is accompanied by gains as well as risks. The physical hazards are generally higher and the metabolic profit lower in the type 1 than in the type 2 diabetic. On the other hand, the level of physical activity desirable for psychologic and social reasons is higher for type 1 diabetics because they are mostly younger.

Before increasing usual patterns of physical activity all diabetes patients should undergo a medical evaluation consisting of a careful medical history and a physical examination focusing on symptoms and signs of disease affecting the heart and blood vessels, eyes, kidneys, feet, and the autonomic and peripheral somatic nervous systems. If the diabetic is older than 35 years, or has had the disease for more than 10 years (type 2 diabetics) or 15 years (type 1 diabetics), or has complications or any additional risk factor for coronary artery disease, he or she should also be subjected to echocardiographic examination and a graded exercise test including ECG and blood pressure measurements (Table 41.3) [131]. Identification of areas of concern will allow appropriate treatment as well as individualized exercise prescription minimizing risk to the patient. As the disease is not stationary, the diabetic ought to see the doctor regularly.

Particularly for the type 1 diabetic patient, who wants to be physically active, it is of utmost importance that he or she — or the parents if the diabetic is a child — has a sound knowledge of the disease with a profound understanding of the interaction between food, insulin, and exercise in the regulation of the plasma glucose concentration (Table 41.1). The patients should be taught how healthy persons respond to exercise and how patients with diabetes differ from healthy individuals. Such knowledge will enable the diabetic to attempt to imitate the normal response by reducing the insulin dose prior to exercise and/or to take extra carbohydrate. However, the patients should also be aware of the fact that the effect of exercise on glucose homeostasis during and after exercise is not accurately predictable and may differ between and even within subjects [213,214]. This underlines the necessity of frequent blood glucose measurements as well as the need for readily available carbohydrate snacks. Furthermore, the diabetic should carry written information about him- or herself and his/her condition. It would appear that it is not possible to give exact recommendations on how to adjust insulin and diet for exercise that are broadly applicable [149]. The diabetic must also individually tailor his or her regimen based on experience. Combination of frequent blood glucose monitoring with multiple short-acting insulin injections or, even better, with insulin pump treatment, offers the highest flexibility in relation to engaging in unplanned exercise and the best glucose control. Rapidly evolving technology allows continuous monitoring of subcutaneous interstitial glucose concentrations and, by use of algorithms, prediction of ongoing development of blood glucose concentrations [215,216]. Proactive reactions can, accordingly, be initiated, and, in consequence, sound physical activity behaviors are increased [215,216]. Provided that the patients have been properly educated, intensified insulin therapy is not accompanied by a high risk of exercise-induced hypoglycemia [217,218]. Some rules are generally agreed upon [131]: If, before exercise, blood glucose is below 5.5 mM, then extra carbohydrate should be eaten before initiation of exercise. If, conversely, blood glucose is above 14 mM urine ketones should be measured, and if they are positive insulin should be taken

and exercise delayed until ketones are negative. Even if ketones are negative, caution must be exerted if blood glucose is higher than 16.5 mM (Table 41.2).

The best glucose control is achieved if exercise is fit into a regular lifestyle in which insulin, food, and exercise are elements of a fixed schedule with the amount and timing of the components carefully adjusted. However, the more diabetics know about their disease, and the more familiar they become with their responses to exercise through blood glucose measurements, the greater a variation in physical activity from day to day they will be able to handle. From a medical point of view the recommended goal would be at least 30 min of exercise a day. For endurance type exercises moderate intensity corresponding to 50–75% of individual maximum aerobic capacity ($\%V_{02max}$, relative workload) is generally recommended. In subjects with a normal heart rate regulation, the relative workload in percent of maximum can be estimated as (actual heart rate minus resting heart rate) $\times$ 100/(maximum heart rate minus resting heart rate). If the individual maximum heart rate is not known, it can be roughly estimated as 220 minus age. Alternatively, perceived exertion may be evaluated from a scale ranging from 6 (very mild) to 20 (extremely heavy), and relative load be calculated as (actual level of exertion minus 6) $\times$ 100/14. It is of note that exercise does not have to be strenuous, even regular walking has beneficial effects, for example on cardiovascular health [166,219]. Much evidence indicates that the overall energy expenditure is more important than exercise intensity when it comes to health benefits [166,219–221]. Over recent years it has been recognized that resistance exercises can be beneficial, for example 2–3 times a week, in the training program of diabetics [126,156,222–225]. All the various skeletal muscle groups of the body may be engaged by this means. Just as for endurance exercises, the intensity of resistance exercises can be varied according to the fitness and health status of the diabetic patient, and responses to exercise can be monitored. Excessive blood pressure increases can be avoided by omitting any breath-holding. In both type 1 and type 2 diabetic patients strength training has been shown to elicit beneficial effects on insulin sensitivity and HbA1c levels similar to those seen with endurance exercise [127,148,151,160,226–228]. In addition, resistance training serves to maintain or improve muscle mass and strength, which is important, for example with aging [126,223,227,229,230]. Recently, short duration but high-intensity exercise has been advocated as a means to improve metabolic regulation in nondiabetics and also in patients with T2DM [231,232]. The advantage being that while this type of exercise induces metabolic adaptations similar to those that can be obtained through more traditional endurance training, it is time efficient and therefore offers a greater likelihood of beginning and maintaining an exercise program as lack of time is a commonly cited barrier to regular exercise participation.

From analysis of the diabetic patient's condition and the demands of exercise, it is possible to predict the extent of a given physical activity that the patient will be able to tolerate. Diabetics in good metabolic control and without long-term complications can exercise on equal terms with healthy subjects. Adjustment of the therapeutic regimen will allow safe participation in all forms of physical activity even during changing daily schedules and preferences. In general, long-term changes in physical activity are difficult to achieve [233]. The fact that personal preferences can be complied with is important for maintenance of a physically active lifestyle. Activities that are considered to be enjoyable, varied, convenient in time and location, and which offer appreciable gains, are supervised and free, and can be performed in groups are likely to achieve the best compliance. In type 2 diabetics, motivational tools, for example pedometers, and an exercise consultation combining motivational theory and cognitive behavioral strategies also promotes an increase in physical activity [233–235]. Particularly in children, interactive computer games requiring vigorous body activity as input may enhance exercise behavior [236]. Appropriate exercise options for diabetics with long-term complications are suggested above and are described in more detail elsewhere [196]. For all kinds of training, in order to prevent musculoskeletal injuries and dropout for other reasons too, progression in exercise intensity and duration should be slow, and each training session should begin and end with muscle stretching and contractions of low intensity. Furthermore, optimum equipment (e.g. shoes) should be used. Exercise, which markedly increases cardiac output, should be avoided in the incubation and fever phases of infectious diseases, and caution should be exerted also in other acute or unstable chronic medical disorders. In case of unusual sensations (e.g. chest pain) exercise must be interrupted.

It is comforting, reassuring, and motivating for the diabetic to know that other patients meet the same troubles as him/her and that the disease does not necessarily restrain desired activities. In this context, the existence of summer camps, where diabetic children meet, play, and learn to handle their disease, should be remembered. Sharing of experiences among physically active people with diabetes may also take place through organizations like the Insulinindependence organization (www.insulindependence.org) the mission of which is to enhance the quality of life for people with diabetes through exercise. Diabetics are involved in all kinds of sports, for example marathon running [237], competitive cross-country skiing [238], scuba diving [215,239], and mountain climbing [240], also at the professional level. There are examples from the past of diabetic athletes, who have become Olympic gold medalists and world champions [241,242], and growing knowledge and technology in diabetes care will enable this to become a more frequent event.

Exercise in the prevention of diabetes

Notwithstanding the therapeutic effect of exercise in patients who have developed diabetes, exercise may be particularly

efficacious if instituted earlier in life. This supposition is in line with the fact that in experimental studies physical activity increases insulin sensitivity and improves glucose tolerance in both healthy subjects and in people with obesity, gestational diabetes, and impaired glucose tolerance as well as in first-degree relatives of patients with T2DM. More support for the ability of exercise to prevent T2DM has come from a multitude of descriptive studies of societies undergoing a transition from traditional lifestyles to more Westernized patterns, examination of migrants from traditional to more urbanized environments and vice versa, comparisons of active rural versus more sedentary urban populations, case-control studies, retrospective cohort studies, and prospective studies of active compared with sedentary individuals. The most powerful evidence has been provided by several nonrandomized or randomized, controlled interventional epidemiologic studies [1,156,243–247]. According to studies the risk of getting T2DM within a 6-year period can be reduced by at least 40% with an active compared with a sedentary lifestyle. Weight loss is not necessary for a beneficial effect of exercise, and an effect can be obtained by mild or moderate exercise, the effect depending on overall energy expenditure rather than on intensity of exercise [219]. While high-intensity low-volume exercise has recently been shown to improve metabolic status in type 2 diabetic patients [231,232] the long-term efficiency of this type of exercise in actual disease prevention or treatment has not yet been established. The most marked benefit of exercise in diabetes prevention has been observed in people with obesity or a family history of diabetes [244,248]. So, obvious target populations for training programs would be people at increased risk of T2DM, for example first-degree relatives, women with gestational diabetes, people with low birth weight or visceral obesity, and certain ethnic groups. However, translation of evidence from structured intensive trials to routine clinical settings is challenging [249].

Sulfonylureas and meglitinides: insights into physiology and translational clinical utility

Harold E. Lebovitz[1] and Arne Melander[2]

[1] State University of New York Health Science Center at Brooklyn, Staten Island, NY, USA
[2] Lund University, Malmö, Sweden

Key points

- Sulfonylureas and meglitinides are effective treatments for hyperglycemia in type 2 diabetes.
- Sulfonylureas and meglitinides bind to specific sites on pancreatic β-cell plasma membrane ATP-dependent potassium channels and close the channels by a glucose-independent mechanism. Closure of the ATP-dependent potassium channel results in membrane depolarization, opening of voltage-gated calcium channels, an increase in cytosolic calcium ion, and migration and exocytosis of insulin granules.
- Sulfonylureas and repaglinide at the appropriate doses improve glycemic control in type 2 diabetes similarly. Differences among the various agents are related to characteristics of: oral absorption, affinities and binding to SUR1 receptor sites, plasma half-life, mechanisms of metabolism, and sites of excretion.
- Side effects of glucose-independent insulin secretagogues are clinically significant hypoglycemia, weight gain, and possibly an increase in cardiovascular mortality.
- Sulfonylureas are unique treatments for diabetes caused by genetic abnormalities of glucose metabolism and ATP/ADP control of insulin secretion.

Historical perspective: the merger of clinical and basic science

There is no better example of the interplay of astute clinical observations leading to basic science research which then opens new insights into basic physiology and pathophysiology than the history of hypoglycemic sulfonylureas. As a consequence of food shortages and poor sanitation during World War II, epidemics of typhoid fever occurred in Europe. In 1942 Marcel Janbon, a clinician at the Clinic of the Montpellier Medical School in France had the occasion to treat such patients with a newly developed sulfonamide (2254 RP) [1]. He noted that many of the patients had adverse reactions such as convulsions and even prolonged comas. A major drop in blood glucose levels was observed in some patients. Dr. Janbon recognized the similarity of those findings to those of his patients taking insulin. He consulted with Professor August Loubatières of the physiology department who immediately undertook animal studies with 2254 RP. On June 13, 1942, Professor Loubatières observed that repeated oral administration of 2254 RP in a normal fasting conscious dog induced a progressive, severe and prolonged decrease in blood glucose. Thus he established the hypoglycemic effects of 2254 RP [1,2]. From 1942 through 1946 by undertaking a series of systematic studies of the effects of 2254 RP and structural analogues, he established that the hypoglycemic property of 2254 RP and its analogues was due to their ability to stimulate the secretion of insulin through a direct action on pancreatic islets. He proposed the use of hypoglycemic sulfonylureas to treat certain forms of diabetes [2].

For the next 50 years sulfonylureas were used to treat patients with T2DM without knowing the mechanism by which they were able to stimulate insulin secretion [3–6]. Additionally, a variety of *in vivo* and *in vitro* extrapancreatic effects of sulfonylureas were recognized, but neither the mechanism of these effects nor their relationships to the pancreatic effects were understood [7,8].

A series of *in vitro* studies in the 1980s established that sulfonylureas were able to stimulate insulin secretion without entering the β cell [7,9,10]. This led to the identification of a sulfonylurea receptor on the β-cell plasma membrane [11,12]. In 1995 the sulfonylurea receptor was cloned and the mechanism of sulfonylurea stimulation of insulin secretion was shown to be mediated by closure of the pancreatic β-cell ATP-dependent potassium (K_{ATP}) channel [13,14]. Subsequent studies have identified multiple variants of the SUR receptor in tissues such as brain, myocardium, vascular endothelium and mitochondria

explaining the mechanism whereby some sulfonylureas may exert extrapancreatic effects [15–17].

Mechanism of action of sulfonylureas and meglitinides

Pancreatic β-cell effects

ATP-dependent potassium (K_{ATP}) channels were discovered in the heart in 1983 [18]. Shortly thereafter, they were recognized in pancreatic β cells [19], brain, skeletal muscle, and many other tissues [15,16,20]. The cloning of the sulfonylurea receptor allowed the subsequent identification that the K_{ATP} channel is a hetero-octamer comprising two subunits: four pore-forming Kir6.x subunits and four regulatory SUR (sulfonylurea receptor) subunits [14,20–22]. Kir6.x is a member of the inward rectifier K^+ channel family; SUR is a member of the ATP-binding cassette protein superfamily.

The K_{ATP} channel functions to regulate potassium ion efflux from the cell and plays a role in maintaining the plasma membrane voltage potential. Closure of the cell membrane K_{ATP} channel causes depolarization of the plasma membrane resulting in opening of plasma membrane voltage-gated calcium channels. Extracellular Ca^{+2} enters the β cell increasing cytoplasmic Ca^{2+} concentration (Figure 42.1). In secretory cells that increases granule exocytosis and hormone secretion (e.g. insulin release from β cells). In muscle cells there is an increase in contractility and in nerve cells there is an increase in signal transmission. The basal state in secretory cells is characterized by open K_{ATP} channels which close during stimulation of secretory activity. By contrast, in tissues requiring high metabolic activity, the K_{ATP} channels are ordinarily closed and open in response to the need to reduce energy requirements (hypoxemia) or to increase blood flow (ischemia) [16,20–22].

The state of the K_{ATP} channel is determined by the regulatory subunits (SUR) which surround the rectifier subunits. The SUR subunit contains two nucleotide binding folds, three transmembrane domains and binding sites which recognize both the sulfonylurea moiety and the benzamido moiety (Figure 42.2) [20–22]. The nucleotide binding sites are located on the cytoplasmic surface of the K_{ATP} channel and recognize the ATP/ADP concentration ratio. Low ATP/ADP ratios are associated with open K_{ATP} channels. Increasing ATP/ADP ratios close increasing numbers of K_{ATP} channels. The ATP/ADP concentration ratio is the physiologic regulator of the state of the K_{ATP} channel. The sulfonylurea and benzamido binding sites of the SUR receptor are on the extracellular surface of the K_{ATP} channel and their activation causes its closure independent of the ATP/ADP concentration ratio. Figure 42.2 is a schematic representation of the SUR 1 and Kir6.2 subunits of the pancreatic β-cell K_{ATP} channel. Site A corresponds to the sulfonylurea binding site and Site B to the meglitinide (benzamido) binding site [21,22]. Drugs can be differentiated into those that bind to the sulfonylurea (A) site, those that bind to the benzamido (B) site, and those that bind to both sites as shown in Figure 42.3.

Oral hypoglycemic secretagogues which bind to either one or both sites cause closure of the pancreatic β-cell K_{ATP} channel similar to but independent of the ATP/ADP concentration ratio. The result is depolarization of the plasma membrane and opening of the adjacent voltage-gated calcium channel (VDCC). Calcium ions from the extracellular compartment enter the β cell and increase the cytosolic Ca^{2+} concentration [23]. The migration of the insulin granule to the plasma membrane and its exocytosis are proportional to the cytosolic Ca^{2+} concentration. The potency and kinetics of the hypoglycemic insulin secretagogues are related to the binding site specificity and kinetics of interaction with the SUR1 subunit. Figure 42.4
Figure 42.1 Scheme of a stimulated β cell. Sulfonylureas stimulate by binding to plasma membrane receptors that are coupled to ATP-dependent K^+ channels. This inhibits efflux of K^+, causing depolarization of the plasma membrane. As a consequence, voltage-gated Ca^{2+} channels open, causing influx of Ca^{2+} into the cytosol, which stimulates extrusion of mature and immature insulin granules. ATP-dependent K^+ channels can also be inhibited by intracellular metabolic events that increase the ATP/ADP ratio. Source: Siconolfi-Baez et al. 1990 [12].

Figure 42.2 Schematic of the Kir6.2 SUR1 subunit of the pancreatic β-cell ATP-dependent K$^+$ channel. The SUR subunit contains three transmembrane domains. There are two nucleotide binding sites on the cytoplasmic surface (NBF-1 and NBF-2). Two binding sites are present (sulfonylurea and meglitinide) which can interact with sulfonylurea and related molecules. The channel can close when ATP/ADP ratios are high or independently of ATP/ADP ratio when activated by molecules which bind to either the sulfonylurea or meglitinide sites. Source: Seino 2012 [22]. Reproduced with permission of John Wiley & Sons.

Figure 42.3 Molecules which bind to either the sulfonylurea (A) site , the meglitinide (B) site or both sites. Binding to either or both sites closes the ATP-dependent channel and stimulates insulin secretion. Source: Modified from Melander et al. [6]. Reproduced with permission of Springer.

Figure 42.4 Displacement of [3H]glipizide from purified plasma membranes from RINm5F-generated insulinomas by glipizide (●), glyburide (x), tolbutamide (▲) and chlorpropamide (○). Data are mean ± SE of three determinations. Source: Siconolfi-Baez et al. 1990 [12].

depicts the binding site specificity of the more commonly used hypoglycemic insulin secretagogues.

There are several additional sulfonylurea binding sites in the β cell, the significance of which are controversial. Studies have shown that 75% of glibenclamide binding to the β cell is to the insulin granule [24]. This binding has been postulated to activate processes which facilitate granule exocytosis. More recently sulfonylureas have been postulated to bind to and activate Epac2, an exchange protein directly activated by cyclic AMP [25]. This protein acts as a guanine nucleotide exchanger for Rap-1 and promotes insulin granule exocytosis [26]. Epac2 is known to play a significant role in cyclic AMP-mediated insulin secretion [26]. Sulfonylurea binding and activation of Epac2 has been controversial with some positive and some negative data [25,27].

The SUR subunit of the K_{ATP} channel of the myocardial (SUR2A) and vascular smooth muscle cells (SUR2B) are isoforms of SUR1. SUR2A has 68% homology with SUR1 and SUR2B differs from SUR2A by 42 amino acid residues in the C-terminus [15,16]. Their amino acid sequences differ somewhat from that of the SUR1 subunit in the K_{ATP} channels of β cells and neurons (SUR1). These differences include the binding site regions for sulfonylureas and meglitinides and provide for individual sulfonylurea-mediated differences in extrapancreatic effects [15,16]. Extrapancreatic effects of sulfonylureas are dependent on the specific SUR subunit of the tissues K_{ATP} channel, the concentration of the sulfonylurea achieved at the tissue's K_{ATP} channel and the affinity of the sulfonylurea for the specific SUR subunit in that tissue's K_{ATP} channel [28–32]. *In vitro* demonstration of an extrapancreatic effect of a sulfonylurea may have no physiologic or pharmacologic equivalent *in vivo* since tissue concentration achieved *in vitro* is many times greater than that achievable *in vivo* and accessibility to the tissue is not limited *in vitro* as it is *in vivo*.

Extrapancreatic effects of sulfonylureas

K_{ATP} channels are present in many cells and regulate a variety of physiologic processes (Table 42.1). The Kir0 subunit has at

least two isoforms and the SUR subunit has three isoforms. Combining different subunit isoforms creates K_{ATP} channels with differing characteristics of the binding sites to serve the physiology of the different tissues. The K_{ATP} channel of the pancreatic β cell is Kir6.2 SUR1, that of myocardial (sarcolemma) and skeletal muscle cells is Kir6.2 SUR2A, that of smooth muscle cells Kir6.2 SUR2B, that of vascular smooth muscle Kir6.1 SUR2B, that of neurons Kir6.2 SUR1, and mitochondrial K_{ATP} channels are closely mimicked by Kir6.1 SUR1 subtype [22].

The K_{ATP} channels in all tissues regulate the extrusion of potassium ions from the intracellular compartment and the flow of extracellular calcium into the intracellular cytosol. Depending on the basal state and physiology of the tissue, these changes influence neuronal activity in the hypothalamus which responds to changes in nutrients (hypoglycemia) or stimuli coming from other neuronal centers (ischemia) [30,31], energy metabolism, contractile force and arrhythmias in the myocardium [32], blood flow in arteries [22], and contractile force in skeletal muscles [22]. The ability of a particular sulfonylurea or meglitinide to affect these activities will depend on the specificity and binding characteristics of the drug for the SUR binding site of the tissue. The concentration of the drug achieved at the binding site may be equally as important as, for example, neuronal activation where the SUR subunit is the same as in the pancreatic β cell.

Pharmacology and clinical pharmacology

Chemistry and structure of sulfonylureas and meglitinides

The sulfonylureas are sulfonamide derivatives (Figure 42.3). For years it was presumed that the hypoglycemic effects of the sulfonylureas required the sulfonylurea moiety. The demonstrations in the 1980s that the nonsulfonylurea analogues of glibenclamide and gliquidone mimic the *in vitro* and *in vivo* effects of their parent compounds on pancreatic β-cell function and insulin release indicated that the structural requirements

Table 42.1 Tissue specificity and physiologic role of K_{ATP} channels in different tissues

Tissue	Rectifier subunit	SUR subunit	Basal state of K_{ATP} channel	Stimulus	Effect
Pancreatic β-cell	Kir6.2	SUR1	Open	Glucose closes	Insulin secretion
Brain	Kir6.2	SUR1	Dependent on ATP/ADP	Hypoxia, hypoglycemia, nerve injury, and nutrient flux open	Counterregulation from hypoglycemia
					Reduces membrane excitability
					Protects from seizures
					Nutrient regulation
Cardiac sarcolemma	Kir6.2	SUR2A	Closed	Hypoxia and ischemia open	Increases K^+ efflux
					Decreases Ca^{2+} entry
					Reduction in action potential duration
					Reduces energy consumption
					Increases re-entrant arrhythmias
Cardiac mitochondria	Kir6.1	SUR1	Closed	Hypoxia opens	Ischemic preconditioning
Skeletal muscle	Kir6.2	SUR2A	Closed	Muscle activity opens	Reduces resting tension
					Improves force recovery
Vascular smooth muscle	Kir6.1	SUR2B	Closed	Hypoxia and ischemia open	Vasodilatation
Smooth muscle	Kir6.2	SUR2B			

for stimulating insulin secretion did not necessarily require the sulfonylurea moiety [33]. This finding has subsequently been explained by the demonstration of the two discrete binding sites on the SUR1 receptor [21,22]. It was also the basis for the development of the meglitinides (repaglinide) [34]. The sulfonylureas have been described as "first generation sulfonylureas" and "second generation sulfonylureas." First generation sulfonylureas, such as tolbutamide and chlorpropamide, have a phenyl ring with simple substituents at one end and an aliphatic side chain at the other end of the molecule (Figure 42.3). In the second generation sulfonylureas, such as glibenclamide (glyburide), glipizide, and glimepiride, the aliphatic side chain has been replaced by a cyclohexyl group and the substituent at the other end is a more complex structure than in the first generation agents. The substitutions markedly increase the molecular affinity of the second generation agents to the SUR1 subunit of the β-cell K_{ATP} channel as compared to the first generation agents and explain their higher intrinsic activity and potency (Figure 42.4).

Pancreatic β-cell K_{ATP} channel and insulin secretion

The pancreatic β cell has multiple modes by which it can increase insulin secretion (Figure 42.5) [21,26,35]. The primary mode is that involved in controlling glucose-mediated insulin secretion and it is regulated by the plasma membrane K_{ATP} channel [26,35]. The ambient plasma glucose concentration determines the pancreatic β-cell ATP/ADP ratio. Glucose entry into the β cell is controlled by the specific glucose transporter, GLUT2, which has high capacity and low affinity for glucose and allows β-cell glucose levels to rapidly equilibrate with plasma glucose levels. Pancreatic glucokinase quickly converts the glucose to glucose-6 phosphate which is oxidized by the mitochondria to generate increased ATP and decreased ADP

levels. The intracellular ATP/ADP ratio is the pancreatic β-cells glucose sensor.

When the plasma glucose is low, the ATP/ADP ratio is low and the K_{ATP} channel is open, is extruding potassium ions from the β cell, and is maintaining the cell membrane voltage potential (Figure 42.6). The adjacent voltage-gated calcium channel is closed and insulin secretion is low. As the plasma glucose increases, the ATP/ADP ratio rises and K_{ATP} channels close (Figure 42.6). The plasma membrane depolarizes, opening the plasma membrane voltage-gated calcium channels. Extracellular calcium enters the cell and increases cytosolic calcium ion concentrations. The increased calcium ion concentration stimulates insulin granule movement to the plasma membrane and its release into the circulation.

Glucose via ATP/ADP stimulates insulin secretion from the cytosolic surface of the K_{ATP} channel. Sulfonylureas and meglitinides bind to the SUR1 receptor on the extracellular surface of the K_{ATP} channel and stimulate insulin secretion independent of the ambient plasma glucose level. These agents are glucose-independent insulin secretagogues.

Acute pancreatic effects of sulfonylureas

Initial studies on the hypoglycemic effects of sulfonylureas demonstrated that functional pancreatic islets were necessary for this action [2]. Sulfonylurea administration has no effect on blood glucose in pancreatectomized or alloxan diabetic animals [2] or in humans with established type 1 [36] or pancreatic diabetes [37]. Acute intravenous or oral administration of sulfonylurea leads to a rapid rise in portal and then peripheral insulin and C-peptide levels in normal or type 2 diabetic humans or animals [38]. Direct stimulation of insulin release by sulfonylureas has been demonstrated *in vitro* utilizing perfused pancreas preparations, isolated pancreatic islets, and β-cell cultures [4,39]. Sulfonylurea stimulation of insulin secretion
Figure 42.5 Multiple modes of insulin secretion. Glucose stimulation of insulin secretion is mediated by the ATP/ADP ratio regulation of the ATP-dependent K^+ channel. Extracellular glucose is transported into the β cell by the GLUT2 transporter, is phosphorylated by glucokinase and generates ATP via the electron transport chain. High ATP/ADP ratios cause closure of the channel. Sulfonylureas and meglitides cause closure of the ATP-dependent K^+ channel independent of glucose regulation of ATP/ADP ratio. Incretins bind to G-protein regulated cAMP-dependent receptors. Their activation increases protein kinase A-regulated pathways and amplifies insulin secretion in the presence of elevated plasma glucose levels. Granule migration is facilitated by Epac2 which is activated by cAMP and perhaps sulfonylureas.
Figure 42.6 Coordinated regulation of ATP-dependent K^+ and voltage-gated Ca^{+2} channels in various tisses. Low ATP/ADP levels are associated with low glucose (β cells), low energy requirements (heart), hypoxia (heart), and ischemia (heart). Such states are characterized by high potassium extrusion, maintainence of membrane potential, and low intracellular Ca^{+2}. High ATP/ADP levels are associated with hyperglycemia (β cells), increased energy requirements, normal heart, normal oxygenation and normal blood flow. Potassium extrusion is minimized, Ca^{+2} entry into the cytoplasm is maximized, action potentials are normal and energy expenditure is high.

from normal β cells is usually weaker than nutrient stimulation, but the reverse is frequently true with diabetic β cells.

A number of observations had suggested that the initial event in sulfonylurea stimulation of insulin secretion involved binding of the sulfonylurea molecule to a specific site on the β-cell plasma membrane. Early studies of the distribution of tolbutamide *in vivo* concluded that the drug was restricted to the extracellular compartment with the possible exception of the liver [7]. The uptake of [35S]tolbutamide into microdissected pancreatic islets was found to be identical to that of markers known to equilibrate with the extracellular space [4]. When perfused through isolated rat pancreas, dextran-linked tolbutamide was shown to be as effective as tolbutamide in stimulating first-phase insulin release [10].

Pursuing the concept that sulfonylurea action involves drug interaction with the plasma membrane, several groups of investigators demonstrated that radiolabeled sulfonylureas such as [3H]glipizide or [3H]glibenclamide bind to purified plasma membranes from either rat insulinoma or transformed hamster tumor β cells with characteristics that are compatible with specific receptor binding [11,12]. Displacement by sulfonylureas occurs in proportion to their activity (Figure 42.4). Patch clamp techniques have shown a potency order of glibenclamide > glipizide > tolbutamide in the inhibition of the ATP-dependent potassium current in insulin-secreting cells [11].

Within several years, the sulfonylurea binding site was isolated, cloned and identified as the SUR subunit of the β-cell plasma membrane K_{ATP} channel [13,14]. Sulfonylurea binding to the K_{ATP} channel initiates events similar to those occurring with glucose stimulation (Figure 42.1). Sulfonylureas inhibit 86Rb efflux (used as a tracer for K+ movement) from islets

incubated at basal glucose concentrations [39]. The stimulatory effect of sulfonylureas on insulin secretion is abolished in Ca^{2+}-deprived media [23], and blockage of Ca^{2+} entry by agents such as verapamil causes a dose-dependent inhibition of sulfonylurea-mediated insulin secretion [23]. Sulfonylureas cause a two- to threefold increase in β-cell cytosolic Ca^{2+} as determined by quin-2 fluorescence [23,39]. Thus, the ion flux changes seen with sulfonylurea stimulation of β cells are similar to that following glucose stimulation. In both instances the rise in cytosolic Ca^{2+} activates the microtubular-microfilamentous system in β cells through one or more of several proposed mechanisms involving protein kinase phosphorylation [39].

While the delineation of the interaction between sulfonylureas and the β-cell plasma membrane K_{ATP} channel explains much of the mechanism by which sulfonylureas stimulate insulin secretion, a number of questions and observations remain unanswered. Several studies have demonstrated that as much as 75% of glibenclamide that attaches to the β cell is actually bound to β-cell granules [24]. These data are consistent with an observed direct effect of sulfonylureas in stimulating the exocytotic process itself. Some studies have suggested that sulfonylureas bind to a 65-kDa receptor in the β-cell granule membrane and activate granular CIC-3 chloride channels which are postulated to promote acidification of the granules which then gain release competence. As previously noted, Zhang and coworkers have recently described a direct effect of sulfonylureas in activating Epac2 which is known to be involved in cyclic AMP-mediated β-cell granule migration and release [25].

The K_{ATP} channel model does not explain the known differences between nutrient-stimulated insulin secretion and sulfonylurea stimulation of insulin secretion. D-Glucose is thought to stimulate insulin secretion by increasing ATP and/or modifying other factors that close the K_{ATP} channel from the cytoplasmic surface of the membrane [39]. Sulfonylureas differ from D-glucose in that they do not increase intracellular ATP or increase the efflux of radioactive phosphate from prelabeled islets [39]. In contrast to glucose, sulfonylureas decrease K^+ inflow into islet cells, increase their Na^+ content, and lower their intracellular pH [39]. Similarly, they do not stimulate proinsulin biosynthesis, neither do they inhibit [2-^{3}H]-adenosine efflux from prelabeled islets. Sulfonylureas only stimulate first-phase insulin secretion [39]. Thus there are many differences between sulfonylurea-mediated and nutrient-mediated insulin secretion.

The presence of sulfonylurea and meglitinide binding sites on the SUR subunit raises the question of whether there are natural ligands for these binding sites. If so, what are they and are alterations in the ligands or in the ATP-dependent potassium channel playing a role in the pathogenesis of β-cell insufficiency in T2DM.

Chronic effects of sulfonylureas

Sulfonylureas have been administered intravenously or orally to humans. Intravenous administration of 1 g tolbutamide bolus

has been used as a test to assess insulin and/or C-peptide secretion [40]. The release of insulin occurs within minutes and is usually complete within 1 hour.

Orally administered sulfonylureas have been used for the chronic treatment of T2DM [3,5,6,22,41]. All sulfonylureas have equivalent effects on insulin release and blood glucose lowering when given at their maximal effective dose. The dose that gives the maximal effect of a given sulfonylurea depends on the affinity and binding characteristics of the specific sulfonylurea for the β cell SUR1 subunit and the pharmacokinetic characteristics and metabolism of the drug. Sulfonylureas can be clinically classified by their duration of action and their mechanism of metabolism and excretion.

In numerous clinical studies it was shown that chronic treatment with sulfonylureas, in contrast to acute treatment, resulted in improved glycemia but with less rather than more insulin secretion [3,8]. Similarly when patients on chronic sulfonylurea therapy showed deteriorating glycemic control it was assumed that the sulfonylurea drugs had lost their insulin secretory activity. Assessments of the chronic effects of sulfonylureas on insulin secretion in patients with T2DM have been difficult to interpret because the magnitude of sulfonylurea stimulation of insulin secretion is influenced by many factors. Some of the factors that influence insulin secretion during chronic sulfonylurea therapy are (a) the intrinsic effect of sulfonylureas on β-cell insulin secretion; (b) the level of glycemia attained during the sulfonylurea stimulus for insulin secretion; (c) the degree of chronic fasting hyperglycemia, which itself may cause inhibition of insulin secretion (glucose toxicity); (d) the stage of glucose intolerance (the functional state of the β cells); and (e) tachyphylaxis to sulfonylureas during chronic, continuous sulfonylurea therapy.

Many studies in type 2 diabetic patients indicate that chronic sulfonylurea treatment increases the ability of the β cell to respond to a fixed stimulus. Porte and colleagues have defined the insulin secretory responses of nonglucose stimuli at different ambient glycemic levels in normal subjects and in patients with T2DM [42]. Normal individuals have an increase in insulin secretion stimulated by intravenous arginine or isoproterenol during an acute intravenous tolbutamide infusion, provided that the plasma glucose level is clamped, but not if it is allowed to fall [42]. It was also shown that 4 of 9 type 2 diabetic patients treated with chlorpropamide for 12–16 weeks had an increase in nonglucose-mediated insulin secretion when their pre-treatment glycemic values were restored [43]. The same phenomenon may explain why type 2 diabetic patients on chronic sulfonylurea therapy will show a rise in nutrient-mediated insulin responses immediately following discontinuation of sulfonylurea therapy [44]. A chronic effect of sulfonylurea therapy to increase the insulin secretory capacity of laboratory animal pancreas to stimuli has not been observed; rather, nutrient-stimulated insulin secretion is decreased.

Studies in type 2 diabetic patients with normal or mildly elevated fasting plasma glucose concentrations show that the

degree of the nutrient-evoked rise in plasma glucose is a major determinant of insulin secretion [5]: thus, a lesser rise such as that occurring during chronic sulfonylurea therapy will result in less secretion.

The chronic level of fasting hyperglycemia is as important as the nutrient-evoked rise in plasma glucose in determining insulin secretion. In this case, however, the higher the fasting plasma glucose value, the lower the nutrient-mediated insulin secretion. A reduction in fasting hyperglycemia by any form of therapy (diet, drugs, or insulin) results in increased glucose-mediated insulin secretion [45]. Exhaustive experimental and clinical data support the concept that chronic hyperglycemia itself inhibits glucose-mediated insulin secretion [46]. Apparently, reduction of fasting and postprandial hyperglycemia in type 2 diabetic patients by any modality can either increase or decrease glucose-mediated insulin secretion.

The question of sulfonylurea tachyphylaxis has been raised by Karam et al. [47], who studied the acute insulin secretory response to intravenous tolbutamide or glucagon in 10 type 2 diabetic patients, before, during, and after tolazamide therapy. They found that chronic tolazamide therapy abolished the insulin secretory response to tolbutamide but not to glucagon, and they also showed that the acute response to tolbutamide reappeared after cessation of tolazamide therapy. They concluded that chronic continuous sulfonylurea therapy may blunt the acute insulin secretory response to sulfonylurea. *In vitro* studies have shown that prolonged incubation of β cells with sulfonylureas causes a disturbance in the assembly and functional activity of the ATP-dependent potassium channel [48]. It is unclear whether this mechanism is operative in humans. Another possibility is that this phenomenon could be explained by downregulation of the SUR1 receptor. Support for this assumption can be obtained from two studies discussed subsequently which showed that increases of dosage and sulfonylurea steady-state concentrations over a certain level impaired rather than improved glucose and insulin responses.

This complexity explains why so much controversy exists as to whether the primary action of chronic sulfonylurea therapy is increased insulin secretion and why there has been continuing interest in whether extrapancreatic effects of sulfonylureas are clinically meaningful.

Effects on the secretion of insulin precursors

Small amounts of insulin precursors, particularly intact proinsulin and 32/33 split proinsulin, are released along with insulin. The proportions of these precursors relative to intact insulin are increased in type 2 diabetic subjects [49] and it has been suggested that this reflects disordered β-cell function. In addition, the levels of plasma proinsulin and 32/33 split proinsulin correlate more closely with cardiovascular risk factors in T2DM than do those of insulin itself. Recent studies indicate that sulfonylurea treatment does not increase the concentrations of 32/33 split proinsulin in type 2 diabetic subjects [50–53]

although insulin and proinsulin levels are enhanced. The ratio of proinsulin to insulin in plasma is unaltered by sulfonylurea treatment [50–53].

Effects on proinsulin biosynthesis

A major difference between sulfonylurea-stimulated insulin secretion and nutrient-stimulated insulin secretion is that sulfonylureas cause only first-phase insulin release (preformed insulin); whereas nutrients stimulate both first-phase and second-phase insulin release. Second-phase insulin release consists largely of newly synthesized insulin. The explanation for the failure of sulfonylureas to stimulate second-phase insulin release may be found in studies utilizing models *in vivo* and *in vitro* of animal perfused pancreas, isolated islets, or islet cell cultures, which have shown that sulfonylureas inhibit the biosynthesis of proinsulin [51,52].

Effects on glucagon and somatostatin secretion

Normal α cells do not appear to have functional ATP-sensitive potassium channels and do not show significant *in vitro* effects of sulfonylureas in regulating glucagon secretion. However, several studies in humans show that glibenclamide treatment causes impairment of glucagon secretion in response to insulin-induced hypoglycemia [54–56]. The mechanism whereby sulfonylureas reduce glucagon secretion is thought to be an increase in intra-islet insulin flow from β cells to α cells. δ-Cells contain K_{ATP} channels with SUR subunits. Sulfonylureas stimulate pancreatic δ-cell somatostatin release [54,56] but it is not clear whether this plays any part in their antidiabetic actions.

Extrapancreatic effects of sulfonylureas

Sulfonylurea drugs have been investigated extensively for extrapancreatic actions [8,57]. Most studies demonstrating such actions have utilized organ perfusion, cell culture, or subcellular preparations from laboratory animals. Some have shown extrapancreatic effects with concentrations of sulfonylureas far in excess of ordinarily attainable therapeutic plasma levels. Studies *in vivo* have frequently failed to validate that the action is a primary one rather than a consequence of better glycemic regulation due to increased insulin secretion. The two sulfonylureas that have been promoted most as having clinically significant extrapancreatic effects in humans are gliclazide [22] and glimepiride [58,59].

As sulfonylureas lower blood glucose only in the presence of a functioning pancreas, it is difficult to attribute a meaningful antidiabetic action to an extrapancreatic effect that occurs in the absence of insulin [59]. Thus, a primary action in increasing fructose 2,6-bisphosphate in the liver with subsequent stimulation of glycolysis and inhibition of gluconeogenesis, although of interest, is unlikely to be a significant component of sulfonylurea antidiabetic action. A similar analysis can be made for primary actions on muscle or adipose tissue.

Effects on insulin action

An extrapancreatic action of sulfonylureas that may have a meaningful antidiabetic effect is the potentiation of insulin action. Such an action was described in 1955 and has been controversial ever since. The clearest demonstrations of sulfonylurea potentiation of insulin action have been carried out in animal models. Experiments utilizing *in vitro* mouse diaphragms or organ cultures with rat adipose tissue have demonstrated that ordinary doses or concentrations of sulfonylureas potentiate insulin-mediated 2-deoxy-D-glucose uptake following a latent period of about 12 h [60]. One study suggested that this is attributable to sulfonylurea potentiation of insulin-mediated translocation of the glucose transporter from intracellular storage sites to the plasma membrane [61].

Putnam et al. [62] utilized the euglycemic insulin clamp at physiologic insulin levels in normal dogs and showed that 2 weeks' treatment with glipizide caused a twofold increase in insulin-mediated glucose disposal. The chronic treatment caused no significant alterations in plasma glucose or insulin.

Studies in patients with T2DM that have attempted to demonstrate sulfonylureas potentiation of insulin-mediated glucose disposal have reported diverse results. Some show that sulfonylurea treatment increased insulin-mediated glucose disposal, but only in patients who have increased insulin secretion [63]; the improved glucose disposal is attributed to higher plasma insulin levels. In a study on insulin-treated type 2 diabetic subjects who had little or no remaining endogenous insulin, sulfonylurea failed to evoke any glucose reduction [64]. Other studies show that sulfonylurea treatment increases insulin-mediated glucose disposal, but the improvement was attributed to the effect of better glycemic regulation. Finally, there are studies in which sulfonylurea treatment improves glycemic control, increases insulin-mediated glucose disposal, and the effects do not correlate with improved insulin secretion, suggesting that true sulfonylurea-induced potentiation of insulin action does occur in some patients with T2DM [65,66].

The liver may be a site of sulfonylurea potentiation of insulin action. Sulfonylureas have been reported to potentiate insulin-mediated glycogen and lipid synthesis. These effects have been described in hepatic cell cultures. Clinical studies suggest that the reduction in fasting hyperglycemia during sulfonylurea treatment can be attributed in part to potentiation of insulin action on glycogen synthesis and gluconeogenesis [64]. Detailed discussions of the relative roles of pancreatic versus extrapancreatic mechanisms in the antidiabetic action of sulfonylureas are available in several reviews [57,67].

The mechanisms of the various extrapancreatic actions of sulfonylureas have not been defined. ATP-dependent potassium channels and specific plasma membrane sulfonylurea binding sites have been found in many tissues, as noted in Table 42.1. They have not been found in liver cells and are present in very minimal quantities in skeletal muscle cells. There is no evidence to suggest that ionic fluxes have any role in mediating the extrapancreatic effects described. The insulin-potentiating action of sulfonylureas has a latent period of several hours, and this effect is blocked by cycloheximide, indicating that new protein synthesis may be necessary for that effect to occur [68].

The effect of sulfonylureas in potentiating insulin action on muscle, adipose tissue, and liver has raised the issue of whether these effects are mediated by a direct action in increasing insulin binding by the insulin receptor (an increase either in receptor number or in affinity) or through post-receptor mechanisms. Studies *in vivo* in which insulin binding is assessed are invalid to answer this question because changes in plasma insulin levels will influence the number of insulin receptors, and measurements of insulin binding to circulating monocytes or adipose tissues may not reflect what is occurring at liver and muscle cells. Assessment of insulin binding to fibroblasts in culture has little physiologic meaning. Several studies *in vitro* indicate that the effect occurs at a post-receptor site [57].

Effect on systemic availability of insulin

One of the earliest extrapancreatic actions of sulfonylureas to be described was inhibition of insulinase, particularly in the liver [69]. Later studies disputed these data, and the idea was abandoned. However, several recent studies suggest that at least glipizide [70,71] and glibenclamide [72] increase the systemic availability of insulin through reduction of the hepatic extraction of insulin secreted from the pancreas. It is not known whether the effect is a primary one, for example inhibition of hepatic insulinase or displacement of insulin from hepatic binding sites, or is secondary to the increased rate of insulin secretion subsequent to sulfonylurea stimulation of the β cells [71]. If the increased systemic availability were attributable to displacement of insulin from hepatic insulin receptors, it is also possible that such displacement may reduce the effect of insulin exerted on the liver and hence would lead to an increased hepatic output of glucose, provided that the displacement was extensive enough. Such a phenomenon would help to explain why high doses of sulfonylurea may impair instead of improve blood glucose control [73,74].

Effects on blood lipids

Sulfonylurea treatment has been reported to have beneficial, neutral, or adverse effects on blood lipids [5,6]. It seems unlikely, therefore, that sulfonylureas have direct effects on very low-density lipid triglycerides, low-density lipid cholesterol, or high-density lipid cholesterol.

Effect on fibrinolysis

A recent study on bovine aortic endothelial cells indicated that certain sulfonylureas may enhance fibrinolysis and that the fibrinolytic mechanism is associated with sulfonylurea-enhanced production of plasminogen activator [75].

Differences in extrapancreatic effects

Some extrapancreatic effects of sulfonylureas are related to parts of the molecule other than the sulfonylurea core and are

therefore unrelated to the antidiabetic action. These extrapancreatic effects may confer unique advantages or disadvantages to a particular sulfonylurea. Chlorpropamide facilitates both the release and the tubular action of vasopressin, causing water retention and hyponatremia in certain patients [76]. Sulfonylureas increase the synthesis and secretion of plasminogen activator from bovine aortic endothelial cells, but the potency is unrelated to the blood glucose lowering activity [75]. The spectrum of action of glibenclamide on the myocardium differs from that of tolbutamide and glimepiride, as discussed in a later section. The clinical potential of many of these differences has yet to be explored.

Clinical aspects of sulfonylurea therapy

Knowledge about the clinical effects of sulfonylureas can be divided into that obtained prior to and after 1995. Studies from the 1950s through 1995 were primarily observational with little of the rigorous design and implementation of current studies. Endpoints were primarily changes in fasting blood glucose levels with values $<100\,mg\,dL^{-1}$ being defined as excellent, between 100 and $130\,mg\,dL^{-1}$ as good, and $>130\,mg\,dL^{-1}$ unsatisfactory [77]. Those early studies can be summarized as follows. Sulfonylureas were effective in improving glycemic control in patients with T2DM with 60–65 % achieving excellent or good control [77–79]. Sulfonylureas increased insulin secretion by a glucose-independent mechanism. Sulfonylureas had their primary effect in lowering fasting plasma glucose through decreasing hepatic glucose production [80–82]. Sulfonylureas had only a slight effect in decreasing postprandial glucose excursions because they did not significantly improve the delay in meal-mediated insulin secretion which is characteristic of T2DM [83]. They significantly increased late meal-mediated insulin secretion which frequently led to hypoglycemia [82,83]. Twenty to 25% of patients initially had little or no improvement in glycemic control (primary failures) [79,84,85]. An initially successful therapeutic response to sulfonylureas was often followed by secondary failure which occurred at a rate of 5–10% per year [79,84,85]. The secondary failure rate was similar for all of the first generation sulfonylureas [86].

Since 1995, studies have utilized changes in HbA1c as the primary efficacy of sulfonylurea therapy. It is important in evaluating such studies to recognize that for all therapeutic treatments, the decrease in HbA1c is a function of the starting (baseline) HbA1c [87]. That is, the higher the starting HbA1c the greater the decline and the lower the starting HbA1c the less will be the decline. This observation suggests that the therapeutic response to an antihyperglycemic agent is a composite of the agent's mechanism of action and the improvement in glucose toxicity that occurs from the treatment. The importance of this observation is that therapeutic agents can only be compared in the same, randomized, controlled clinical trial. When sulfonylureas are used as primary therapy added to patients inadequately controlled by

lifestyle modification, the mean decrease in HbA1c is 1.5% at a mean baseline HbA1c of 8.5% [65,81,82]. When added as a second or third agent for treatment, the incremental decrease in HbA1c is likely to be 0.6–0.8% [41,82,88].

Much of our long-term information about sulfonylurea therapy for patients with T2DM comes from the United Kingdom Prospective Diabetes Study (UKPDS) which was started in the late 1970s and concluded in 1997. This study recruited slightly more than 5000 newly diagnosed type 2 diabetic patients and after a 3-month diet intervention, randomized those who were still hyperglycemic to either continued lifestyle modification without drug addition ("conventional treatment") or continued lifestyle modification to which was added a sulfonylurea (glibenclamide, chlorpropamide, or glipizide) or insulin ("intensive control") [89,90]. Some overweight patients were randomized to addition or no addition of metformin, and in a substudy, some normal-weight and overweight patients already on sulfonylurea were also randomized to addition or no addition of metformin, to enable assessment of combination treatment [89,90]. The patients were followed for a mean of 11 years and the endpoints were the development of clinically significant diabetic complications. The aim was to achieve a fasting plasma glucose $<6\,mmol\,L^{-1}$.

Sulfonylurea treatment achieved the same glycemic control over the 10 years as did insulin treatment, with less increase in body weight [90] (median HbA1c: chlorpropamide 6.7%, glibenclamide 7.2%, insulin 7.1%, conventional 7.9%). These data are somewhat misleading since glycemic control in all groups deteriorated with time. For example in the intensively treated groups which included those randomized to sulfonylureas, median HbA1c increased for each successive 5-year treatment period (6.6% in the first 5 years, 7.5% in the second 5 years, and 8.1% in the last 5 years) [91].

A detailed analysis of the UKPDS monotherapy data showed that the percentage of patients treated with sulfonylureas that achieved a HbA1c <7% were 50% at 3 years, 34% at 6 years and 24% at 9 years [92]. An analysis of 1305 patients treated with glibenclamide or chlorpropamide over 6 years showed that loss of sulfonylurea responsiveness was related to higher initial plasma glucose concentrations at randomization, younger age of presentation of diabetes, lower initial β-cell reserve as measured by the HOMA model, and those randomized to glibenclamide compared with chlorpropamide [93]. For example, 61% of patients with a fasting plasma glucose $\geq10\,mmol\,L^{-1}$ required additional antihyperglycemic therapy by 6 years. By contrast only 23% required additional therapy if the fasting plasma glucose was $<7.8\,mmol\,L^{-1}$.

During the first 6 years of the UKPDS, β-cell function as estimated by the HOMA model was assessed in 511 patients allocated to sulfonylurea therapy and compared to that of 376 patients allocated to diet [94]. At randomization the patients on conventional therapy (diet without drugs) had 51% of normal β-cell function and the sulfonylurea patients 46%. The β-cell function of the patients on diet decreased progressively

over the 6 years to 28%. The mean β-cell function in the sulfonylurea-treated patients rose to 78% at 1 year but then decreased progressively and was 52% at 6 years. The data were interpreted as consistent with an inability of sulfonylureas to change the progressive β-cell loss that occurs in T2DM. Oral antidiabetic therapy failure most likely is the result of the progressive loss of β-cell function with time.

Sulfonylurea treatment has been shown to cause a near-euglycemic remission, which persists for at least several months and possibly years after the drugs have been discontinued. This was well documented by Singer and Hurwitz in 1967 [95] following tolbutamide (31% of patients) or chlorpropamide treatment (17% of patients), and later confirmed by Lev-Ran [96]. It is likely that the remission is related to excellent glycemic regulation rather than to a specific effect of sulfonylurea treatment. The recent studies of remission in African-American patients with T2DM [97–99] and those in Chinese patients [100] support the concept that early attainment of euglycemia by either insulin or sulfonylureas in new-onset T2DM can lead to remission of diabetes with improved insulin secretory function for several years.

A major shortcoming of sulfonylurea treatment appears to be their short durability of glycemic effect. This was initially recognized by the high secondary failure rate of sulfonylurea therapy [79], and then quantified by the UKPDS data [93,94]. A 5-year study (ADOPT) compared the durability of effect of glibenclamide to that of metformin and rosiglitazone [101]. The sulfonylurea was superior in both glucose and HbA1c lowering at 6 months, but lost most of its effectiveness by 18 months of treatment. The other drugs showed significantly greater durability of glycemic lowering beyond 1 year than glibenclamide. One mechanism by which sulfonylureas lose their effectiveness in treating hyperglycemia is postulated to be related to long-term toxic effects on the pancreatic β cells leading to an increase in apoptosis [102,103].

Patients who are most likely to show an excellent or good glycemic response to sulfonylurea therapy are those who have relatively recently diagnosed T2DM, have mild to moderate fasting hyperglycemia (fasting plasma glucose levels below $12.5 \, \mathrm{mmol \, L^{-1}}$) on dietary management, have a good β-cell reserve as reflected by high C-peptide levels, have a normal weight or are moderately obese, and have either never been treated with insulin or are taking less than 30 U of insulin daily [81,82].

Similarities and differences among sulfonylureas

All sulfonylureas appear to have the same mechanism of action on the β cell and at appropriate dose will equally stimulate insulin secretion. Differences in the clinical characteristics of individual sulfonylureas are due to variability in rates of absorption, plasma half-life, binding affinities and kinetics

of interactions with the SUR binding sites, mechanisms of metabolism, and routes of excretion [5,81,82]. Side effects can be related to affinities and binding kinetics to SUR isoforms in extrapancreatic tissues or unrelated to K_{ATP} channel binding and attributable to molecular structures other than those responsible for K_{ATP} channel binding. Characteristics of the commonly prescribed sulfonylureas are detailed in the following sections.

Tolbutamide

Tolbutamide in various formulations from different manufacturers is in use in many countries. There are differences in absorption rate between formulations [104,105] and this may be important, as more rapid absorption may signify a higher efficacy in reducing postprandial hyperglycemia. Tolbutamide is more rapidly absorbed than chlorpropamide [6], but less rapidly than glipizide. Many, but not all, tolbutamide formulations have a high degree of absorption, but there are no appropriate estimates of the absolute bioavailability of this drug. Concomitant food intake may not delay the absorption of tolbutamide, but its efficacy may be improved if the drug is given half an hour before meals rather than with meals.

The volume of distribution of tolbutamide is small, like that of all other sulfonylureas. It is highly bound to plasma albumin, but the extent of protein binding decreases with age, roughly in parallel with decreasing plasma albumin levels [104]. Tolbutamide is completely metabolized, mainly to hydroxytolbutamide and subsequently to carboxytolbutamide, both of which have little or no activity. Metabolism occurs by oxidation, and it has been suggested that the first oxidative step to hydroxytolbutamide is genetically polymorphic with a trimodal distribution [106]. Phenylbutazone [104] and cimetidine [104] may inhibit the metabolism of tolbutamide.

Little, if any, tolbutamide is excreted unchanged. The metabolites are excreted by the kidney [104].

The usual dosage of tolbutamide is 0.5–1.0 g three times daily.

Chlorpropamide

Chlorpropamide is more slowly absorbed than tolbutamide and has the longest elimination half-life of all sulfonylureas. This leads to pronounced accumulation with very small fluctuations over the day within the individual [107]. Therefore, the elimination rate is the major determinant of its effect, whereas variations in its rate of absorption are unimportant. Hence the timing of the daily dose is irrelevant, and it is also irrelevant whether chlorpropamide is ingested before or with breakfast. There are no data on the absolute bioavailability of chlorpropamide. Like that of all other sulfonylureas, the volume of distribution is small, but its binding to plasma albumin is less pronounced. Chlorpropamide undergoes extensive, albeit slow, metabolic transformation. This occurs by oxidation to 2-hydroxychlorpropamide, 3-hydroxychlorpropamide, and *p*-chlorobenzene sulfonylurea [104]. It is not clear whether the hydroxylated metabolites are active; however, they are more

rapidly eliminated than the parent drug, at least in subjects with normal renal function.

A significant portion of chlorpropamide is excreted unchanged by the kidneys [104]; this proportion can be increased by alkalinization and reduced by acidification of the urine [6,104]. The elimination half-life of chlorpropamide is long but variable (24–48 h), partly because of variations in the excretion rate of the unchanged compound and partly because of variations in the metabolic turnover rate. This also helps to explain why there is a very large inter-individual variation in the steady-state plasma concentrations of chlorpropamide during treatment [107].

The usual dosage of chlorpropamide is 250–500 mg once daily.

Chlorpropamide is more commonly associated with long-lasting hypoglycemic events than are most other sulfonylureas, possibly with the exception of glibenclamide (see later); this is probably related to the slow elimination and pronounced accumulation of the drug. On the other hand, chlorpropamide is the only sulfonylurea with elimination that can be enhanced by forced diuresis and urine alkalinization [6,104]. The pronounced accumulation may also help to explain why chlorpropamide, more often than other sulfonylureas, is involved in events of ethanol-provoked facial flushing.

A major unique side effect of chlorpropamide treatment is water retention and hyponatremia. This is related to stimulating the release of vasopressin from the posterior pituitary and to potentiating vasopressin action on the renal tubule [76]. This side effect might explain the observation in the UKPDS that the patients randomized to chlorpropamide had significantly higher systolic and diastolic blood pressures throughout the study than those assigned to glibenclamide, insulin, or conventional treatment [91]. Alcohol-induced facial flushing is a complication of chlorpropamide treatment in some patients with T2DM [108]. The mechanism is related to an inhibition of aldehyde dehydrogenase and elevated blood acetaldehyde levels [108]. Alcohol-induced flushing is not unique to chlorpropamide and occurs with a lower frequency with tolbutamide and only rarely with glibenclamide.

The UKPDS clearly showed that chronic chlorpropamide treatment achieves better glycemic control than does glibenclamide (median 10-year HbA1c: 6.7% vs. 7.2%; $p < 0.008$) [91]. Despite the better glycemic control, the chlorpropamide-treated patients had less risk reduction for the progression of retinopathy than did the glibenclamide-treated group [91].

Glibenclamide

The most extensively used sulfonylurea in most parts of the world is glibenclamide (called glyburide in the United States). It was the first "second generation" sulfonylurea to be introduced in clinical practice, and it is one of the most potent. Both nonmicronized and micronized generic formulations have appeared, but it is not clear whether they are fully equivalent to the original products. Although concomitant food intake does not seem to delay the absorption of glibenclamide, its efficacy may be increased if given before meals, at least in the short term. Indeed, 2.5 mg given half an hour before breakfast was more effective than 7.5 mg given together with breakfast [109]. The rate of absorption varies extensively between individuals [110].

Like other sulfonylureas, glibenclamide has a small volume of distribution, and it is very extensively bound to albumin.

Glibenclamide is completely metabolized, mainly by oxidation to two hydroxylated metabolites, both of which have blood glucose reducing activity [111].

About half of a given dose of glibenclamide is eliminated by renal excretion of metabolites, and a significant portion is excreted through the bile. Although renal insufficiency should not alter the elimination rate of this very lipophilic and completely metabolized drug, it may nevertheless increase the risk of hypoglycemia [104]. This may be because renal insufficiency is associated with reduced drug binding to albumin; in addition, renal impairment may lead to accumulation of polar, active metabolites [104].

Both clinical experience and various studies support the view that glibenclamide should be classified as a long-acting sulfonylurea. Indeed, glibenclamide has been associated with long-lasting (and hence dangerous) hypoglycemic reactions more often than other sulfonylureas except, perhaps, chlorpropamide [3,104,112–114].

The usual daily dose of glibenclamide is 1.75–14 mg (micronized) or 2.5–20 mg (nonmicronized), given in a single morning dose or split in a morning and an evening dose.

Glibenclamide and glipizide have been compared. Glipizide releases insulin more rapidly than glibenclamide [112–116]; however, glibenclamide suppresses hepatic glucose output more than does glipizide [115].

In a placebo-controlled study wherein glibenclamide and glipizide were given in a crossover fashion for 6 months, and in which most patients were continuously exposed to either drug, there was no difference in the final mean daily dose, or in final mean blood glucose or hemoglobin levels. Although fasting blood glucose values tended to be lower in patients on glibenclamide and postprandial blood glucose values lower in those on glipizide, neither difference was significant [104].

Despite concerns about the use of sulfonylurea drugs in pregnancy, a comparison of glibenclamide and insulin treatment of 404 women with gestational diabetes showed that both treatments gave equal glycemic control and no difference in maternal and neonatal complications. Thus glibenclamide may be a clinically effective alternative to insulin treatment in women with gestational diabetes [117,118].

Gliclazide

Gliclazide is a rapid-acting and short-acting sulfonylurea that is widely used in some countries, including France and the United Kingdom. Because of the aminoazabicyclo-octyl ring in its chemical structure, gliclazide is thought to have additional benefits in that it can scavenger reactive oxygen species [119].

It is rapidly absorbed, but its absolute bioavailability is not known. Absorption is slower in the elderly [120,121]. Like other sulfonylureas, gliclazide is extensively bound in plasma and has a small volume of distribution [104,121]. It is not known whether intake before meals makes gliclazide more effective than does intake together with meals.

Gliclazide is almost completely metabolized, and the metabolites seem to be inactive [104].

Most gliclazide is eliminated by excretion of the inactive metabolites through the kidneys, but a small fraction is eliminated by the bile [104]. The elimination half-life is short but variable, between 6 and 15 h. Although this might not be expected for a completely metabolized drug, the elimination half-life may be increased in subjects with renal insufficiency [104].

It has been argued that gliclazide offers distinct advantages over other sulfonylureas. Its antioxidant activity is reported to protect pancreatic β cells from the destructive effects of oxidative stress [122,123]. It has been claimed that gliclazide is able to reduce platelet aggregation [124]. However, it is most likely that all sulfonylureas are able to improve platelet aggregation as an indirect effect of improved blood glucose control [6]. There are no comparative studies showing that gliclazide is superior to other sulfonylureas in reducing platelet aggregation. In terms of blood glucose control, gliclazide seems to be as effective as other sulfonylureas [104].

The usual daily dose is 40–320 mg, given in a single morning dose or in the morning and evening.

Gliclazide MR is a modified-release formulation using a hydrophilic matrix allowing a once-daily dosing regimen with optimal and consistent release of gliclazide [125]. The usual dose is 30 to 120 mg once daily. The GUIDE study which compared gliclazide MR to glimepiride showed equivalence in improving glycemic control but 50% fewer confirmed hypoglycemic events with gliclazide MR [126]. Gliclazide MR was the primary agent used in the intensively controlled cohort in the ADVANCE study which was a study to determine the effect of intensive glycemic control compared to ordinary glycemic control on combined microvascular and macrovascular complications in 11,400 type 2 diabetic patients treated for a median of 5 years [127]. The results showed a decrease in early microvascular endpoints. Avogaro has reviewed those data and additional studies that showed the gliclazide has general antioxidant and anti-inflammatory effects [128]. Despite the emphasis on the antioxidant and anti-inflammatory actions of gliclazide, there are no convincing studies that these effects translate into better clinical outcomes in patients with T2DM than other sulfonylureas.

Glipizide

Glipizide is widely used in the United States and in several European countries. It is the most rapidly acting sulfonylurea available, and is also one of the most short-acting [6,104]. Its potency and intrinsic activity are in the same range as those of glibenclamide.

The absorption and bioavailability of glipizide are fast and complete [6,129]. It is more rapidly absorbed when taken before breakfast than when ingested together with breakfast, and intake before breakfast is also associated with a more appropriate timing of insulin release relative to the meal, and with an enhanced efficacy of the drug [112]. Its absorption rate correlates with its efficacy [130], and pronounced hyperglycemia may reduce the absorption rate [131].

Glipizide has been shown to improve the acute insulin release in response to a meal [130], and this capacity may be maintained during long-term therapy, at least when the exposure is discontinuous [132,133]. This is interesting in view of the possibility that chronic, continuous sulfonylurea exposure may desensitize the β cell to sulfonylurea stimulation [6,47,133].

The volume of distribution of glipizide is small, like that of other sulfonylureas, and the binding to albumin is very extensive [104].

Glipizide is completely metabolized, mainly by oxidative hydroxylation [104]. The metabolites appear to be inactive [104].

Glipizide is rapidly eliminated with a half-life of 1–5 h. The half-life does not seem to increase with age. Renal insufficiency does not seem to alter the elimination rate of glipizide. These facts may explain why glipizide seems to carry a lower risk of long-lasting hypoglycemia than do glibenclamide and chlorpropamide.

Although glipizide is rapidly eliminated, a morning dose of 7.5 mg or more maintains effective plasma concentrations for more than 12 h [6,133,134]. This may help to explain why glipizide, despite its short half-life, can be equally effective when given once daily or three times daily [133,134]. On the basis of available documentation, dosage should be in the range of 2.5–10 mg daily, either as a single morning dose half an hour before breakfast or divided in a morning and an evening dose. In the United States, the official maximum dose is 40 mg, but there is very limited support for increased efficacy with daily doses over 10–15 mg. Instead, dose increase from 15 to 25 mg d^{-1} has been found to impair rather than improve glucose control [73], and a placebo-controlled study using 3-month periods of glipizide at 10, 20, and 40 mg daily showed impaired glucose and insulin responses above 10 mg daily [74]. On the other hand, ethnic differences may exist in the disposition and effect of sulfonylureas, and hence in appropriate dosage.

Glimepiride

Glimepiride is a second generation sulfonylurea that differs structurally from glibenclamide in its two side chains. It is rapidly and completely absorbed after oral administration. Peak serum concentrations are achieved at 2–3 h [135]. When glimepiride is taken with meals the time to reach the maximum concentration and the concentration achieved are decreased by 10% [135]. Plasma protein binding of glimepiride is >99% and the volume of distribution is small. The elimination half-life is 5–9 h [135]. Glimepiride is completely biotransformed by oxidative metabolism (CYP2C9) in the liver and

conversion to a carboxyl derivative by cytosolic enzymes [135]. The hydroxylated metabolite has hypoglycemic activity. The hydroxymetabolite is excreted in the urine (60%) and the carboxymetabolite in the feces (40%) [135].

Glimepiride has a 2.5- to 3-fold faster rate of association and an 8- to 9-fold faster rate of dissociation from the SUR1 binding sites than does glibenclamide [81]. Glimepiride therefore has a rapid onset of action and is short acting. Glimepiride is equally as effective as glibenclamide and glipizide in improving glycemic control in type 2 diabetic patients [81]. Chronic treatment of type 2 diabetic patients with glimepiride for 3–12 months reduces HbA1c by 1.0– 2.0% depending on the mean baseline HbA1c [81,136]. Glimepiride treatment is associated with far less hypoglycemia than is glibenclamide [81,135]. A recent prospective population-based 4-year study in a region of Germany found severe hypoglycemia incidence of 0.86/1000 person-years for glimepiride and 5.6/1000 person-years for glibenclamide [137].

The presumed advantages of glimepiride over other sulfonylureas are (1) the demonstration that glimepiride has extrapancreatic effects in humans [5,58,138], (2) the observation that glimepiride has relatively low binding to SUR2A and SUR2B and does not block ischemic preconditioning in the heart [139,140], and (3) that glimepiride stimulates first-phase insulin secretion [141]. The extrapancreatic effects described in humans do not appear to be of sufficient magnitude to be clinically significant. The lack of altering K_{ATP} channels in cardiovascular tissues may well be a considerable advantage but more clinical studies are needed. The recently demonstrated stimulation of first-phase insulin secretion is quite small and is of questionable clinical significance.

Glimepiride is started at 1 mg once daily. The usual maintenance dose is 1–4 mg once daily. The maximum recommended dose is 8 mg once daily.

Repaglinide

Repaglinide is a meglitinide analogue. Its mechanism of action is similar to sulfonylureas but it exhibits different pharmacologic properties with regard to its structure, SUR binding characteristics, duration of action and mechanisms of excretion [142]. It binds to the benzamido binding site on the SUR subunit of the pancreatic β-cell K_{ATP} channel. Orally administered repaglinide is rapidly absorbed with peak plasma concentrations achieved at 30–60 min [34]. Bioavailability is 63% and the plasma half-life is approximately 1 h [34]. It is eliminated within 4–6 hours. Its volume of distribution is small and binding to plasma albumin exceeds 98% [34]. Repaglinide is metabolized in the liver by cytochrome P450-CYP3A4 and 90% is excreted through the bile with only 8% excreted in the urine [34]. Repaglinide metabolites are inactive [34].

Repaglinide is a short-acting insulin secretagogue and is usually administered in a dose of 0.5–4.0 mg before each meal [142,143]. Because of its pharmacologic properties, its primary action is to lower postprandial hyperglycemia [142,143]. Despite its short duration of action, repaglinide has a significant effect in lowering fasting hyperglycemia [142,143]. Repaglinide is useful as monotherapy or in combination with metformin or other antidiabetic agents. Its short duration of action and administration prior to each meal makes it an ideal treatment for type 2 diabetic patients with a flexible lifestyle [142,143].

Repaglinide monotherapy has been shown to give the same improvement in glycemic control as glimepiride or glyburide in 12-month studies in type 2 diabetic patients [142,143]. Rates of hypoglycemia with repaglinide were comparable to those seen in comparator trials versus glipizide and less than those versus glyburide [142,143]. Weight gain on repaglinide therapy (2.45 kg yr^{-1}) is less than that occurring with glibenclamide (3.64 kg yr^{-1}) [143]. Repaglinide treatment has not been associated with an increase in cardiovascular events or mortality despite the nonselectivity of its binding to SUR isoforms [142]. Insufficient data are available to compare durability of effect or β-cell survival of repaglinide to the sulfonylureas.

Adverse effects of sulfonylureas

In the past, the frequency of side effects of sulfonylureas were thought to be low, in the range of 3–5% and most adverse effects to be mild and reversible upon withdrawal of the drugs. More recent data from retrospective data analyses and large healthcare databases have revised our opinions and particularly have shown significant complication rates in subsets of the T2DM population. The most serious side effect of insulin secretagogues is hypoglycemia. Weight gain is a modest problem, but its clinical impact can only be estimated. An ongoing controversial issue which persists even after 40 years is whether some sulfonylureas may cause unfavorable cardiovascular effects during episodes of myocardial ischemia.

Hypoglycemia

The incidence of hypoglycemia in patients with T2DM has been estimated to be between 12 and 30%. While mild hypoglycemic events are uncomfortable and worrisome for the patient, it is the major or severe hypoglycemic events (symptoms requiring assistance by a third party) which cause the increased morbidity and mortality and the extensive healthcare costs. The magnitude of the problem of sulfonylurea-induced severe hypoglycemia varies remarkably among the different published reports. Some investigators claim that it is rare and not a major clinical problem, while most others find it to be a frequent and serious complication. In reviewing the available data, it appears that reports from single centers with a limited number of type 2 diabetic patients are less likely to view the risk as serious, while studies from large clinical trials and healthcare databases find severe hypoglycemia to be a significant complication of sulfonylurea therapy.

In the UKPDS study, the rates of any hypoglycemic symptoms were 11.0% for chlorpropamide, 17.7% for glibenclamide, 36.5% for insulin, and 1.2% for lifestyle management. The rates of major (severe) hypoglycemia were 0.4% for chlorpropamide, 0.6% for glibenclamide, 2.3% for insulin, and 0.1% for lifestyle [91]. A US population-based retrospective analysis of the incidence of severe hypoglycemia in older individuals reported rates of 1.23 per 100 person-years with sulfonylurea use versus 2.76 per 100 person-years in insulin users [144]. A retrospective study of 33,243 clinical practice patients taking sulfonylureas in the United Kingdom reported an annual hypoglycemia rate of 1.8% [145]. The rate for those less than 65 years was 1.4% per year and for those 65 years or older 2.0% per year. The rate for glibenclamide was greater than for other sulfonylureas.

Within a large integrated healthcare system (Kaiser Permanente), 985 (10.8%) of 9094 eligible type 2 diabetic survey respondents, reported having had one or more severe hypoglycemic episodes requiring assistance in the preceding year [146]. Of the entire cohort, 22.4% were being treated with insulin, 54.8% were taking an insulin secretagogue, and 22.4% were on other antidiabetic treatments. Severe hypoglycemia was reported in 19% of the insulin-treated patients and 9.6% of the patients taking an oral secretagogue. Severe hypoglycemia occurred as frequently in those with poor glycemic control (HbA1c >9 %) as it did in those achieving near normal glycemic control (7.0–7.9%). In the DARTS/MEMO study from Tayside, Scotland data collected over a 12-month period on severe hypoglycemia that required emergency medical treatment were determined in 8655 patients with diabetes [147]. A total of 244 episodes were recorded in 160 patients comprising 69 (7.1%) with T1DM, 66 (7.3%) with T2DM treated with insulin, and 23 (0.8%) with T2DM treated with sulfonylureas. One in 3 was treated solely by the ambulance service, while the remainder were treated in the hospital. The total estimated cost of emergency treatment for severe hypoglycemia was ≤£92,078 in 1 year. An observational, intensively monitored 9–12-month study in the United Kingdom assessed hypoglycemia in three treatment groups of patients with T2DM (sulfonylurea, insulin for <2 years, and insulin for >5 years) and two treatment groups of patients with T1DM (<5 years and >15 years duration of disease) [148]. The incidence of severe hypoglycemia was the same in patients with T2DM treated with sulfonylureas (7%) as in those treated with insulin <2 years (7%). The incidence calculated to 0.1 and 0.2 episodes per patient-year. It has been estimated that each year >5000 patients in the United Kingdom will experience a severe hypoglycemic reaction caused by their sulfonylurea therapy which will require emergency intervention [149]. Each hospital admission for severe hypoglycemia in 2008 was estimated to cost £1000.

The prevalence of sulfonylurea-associated hypoglycemia requiring hospital treatment has been reported as 0.38 per 1000 treatment-years in Switzerland, 0.19 per 1000 treatment-years in Sweden [150], and 4.2 per 1000 treatment-years in the Swedish island of Gotland, where the use of sulfonylurea is particularly common [114]. The Swiss survey reported a fatality rate of 4.3% among the hospital-admitted patients [113]. In a US survey done in the mid 1970s, 10% of hypoglycemic patients referred to hospitals died, and 3% had permanent neurologic damage [151].

Long-lasting, and hence serious, hypoglycemia occurs more often with long-acting sulfonylureas, such as glibenclamide and chlorpropamide, than with short-acting ones, such as glipizide and tolbutamide [113,114,145,152]. The numbers of serious cases in the Swiss review were 0.38, 0.34, 0.15, and 0.07 per 1000 treatment-years for glibenclamide, chlorpropamide, glipizide, and tolbutamide, respectively [113]. Figures from Sweden for the period 1975–1985 show that the number of long-lasting hypoglycemic cases per million defined daily doses were 0.195 for glibenclamide and 0.184 for chlorpropamide, but only 0.004 for glipizide and 0.072 for tolbutamide [150]. Data from the retrospective elderly type 2 diabetic population in the United States found an incidence of hypoglycemia requiring medical intervention to be greatest with glibenclamide (1.66 episodes/100 person-years) and least with tolbutamide (0.35 episodes/100 person-years) [153]. Chlorpropamide use was associated with an event rate similar to that for glibenclamide, and glipizide use had an event rate that was approximately half that of glibenclamide. A recently reported Swiss study found the incidence of severe hypoglycemia to be threefold greater for long-acting sulfonylureas as compared to short-acting forms [152]. As noted earlier the incidence of severe hypoglycemia in type 2 diabetic patients treated with glimepiride is significantly less than those treated with glibenclamide (0.86 episodes/1000 person-years vs. 5.6/1000 person-years) [154].

A predisposing factor for the development of sulfonylurea-induced hypoglycemia is age: most serious cases in Sweden were patients over 75 years old, 21% of whom were over 85 years old [150]. Other predisposing factors are reduced food intake, intercurrent illness, renal disease, hepatic disease, and cardiovascular disease [113,150,155]. It is of note that patients with mutations in the hepatic nuclear factor 1 alpha gene which is the most common form of maturity-onset diabetes of the young (MODY) are exquisitely sensitive to the hypoglycemic effects of sulfonylureas. Treatment of these patients with sulfonylureas is extremely effective; however, the risk of developing severe hypoglycemia is high [156]. Therefore treatment of these patients should be initiated with low doses of short-acting sulfonylureas. There is no apparent dose relation to the development of severe sulfonylurea-induced hypoglycemia in type 2 diabetic patients: severe and fatal hypoglycemia may occur with low doses of the offending sulfonylurea. Drug interactions frequently may be involved, often involving aspirin, salicylate, or alcohol (see later).

The consequences of severe hypoglycemia include both increased morbidity and mortality and a significant increase in healthcare costs. Patients with diabetes (78.7% type 2) who reported one or more severe hypoglycemic reactions had a

3.4-fold increase in subsequent 5-year mortality compared to those diabetic patients who reported no severe hypoglycemic episodes [157]. These findings are consistent with the increase in cardiovascular morbidity and mortality reported in type 2 diabetic patients in the ADVANCE trial who experienced one or more severe hypoglycemic episodes [158].

Current US data show that the insulin and oral hypoglycemic agents were the second and fourth most common cause of drug-related emergency hospitalizations in patients aged ≥65 years for the period 2007–2009 [159]. The estimated annual hospitalizations for sulfonylurea and insulin-induced severe hypoglycemia were 10,656 and 13,854, respectively (10.7% and 13.9% of all drug-related admissions). Of the patients seen in emergency departments for sulfonylurea-induced hypoglycemia 51.8% required hospital admission. In Korea, 132 of 320 (41.3%) patients treated in an emergency department from 2006–2009 for severe hypoglycemia were taking sulfonylureas as contrasted to 29% being treated with insulin [160]. A similar study in Israel of 102 drug-induced hypoglycemic comas in patients with T2DM found that approximately 60% were due to sulfonylurea treatment [161]. Death occurred in 5 of the 102 patients. Risk factors for sulfonylurea-induced hypoglycemic coma were age older than 60 years, renal dysfunction, decreased intake of energy, infection, and concomitant use of drugs that potentiate hypoglycemia [161].

The recent emphasis on intensive glycemic control has caused a decrease in hospitalizations for hyperglycemia but has increased the hospitalizations for hypoglycemia. An analysis of data from Medicare beneficiaries 1999–2011 calculated the change in hospital admissions for hyperglycemia and hypoglycemia in diabetic patients. From 1999 to 2011 the rate of hospital admission for hyperglycemia fell from 820 to 676 per 100,000 patient-years. During the same time frame, the rate of hospitalization for hypoglycemia went from 367 to 612 per 100,000 patient-years [162].

A vicious cycle of dementia and hypoglycemia is being recognized. A higher risk of hypoglycemia occurs among diabetic patients with dementia (adjusted hazard ratio 3.1) and a higher risk of dementia occurs among diabetic patients with recurrent episodes of hypoglycemia (adjusted hazard ratio 2.1) [163]. The dangers associated with intensification of glucose control with insulin and/or sulfonylurea therapy has focused attention on the fact that goals and types of therapy for many patients with diabetes have been excessive [164].

The impact of the increasing rate of hypoglycemia in patients with T2DM has multiple effects. Severe hypoglycemia adds an additional cost dimension to diabetes care. A 2002 analysis from Germany estimated that the cost of severe hypoglycemia amounted to $44,338/100,000 inhabitants in type 2 diabetic patients versus $8129/100,000 inhabitants in type 1 diabetic patients [165]. A study of the incidence and costs of severe hypoglycemia requiring attendance by emergency medical services in South Central England estimated the annual cost of emergency calls for severe hypoglycemia to be £13.6 million for England [166]. Other consequences of severe hypoglycemia are that fear of hypoglycemia and hypoglycemia itself is a significant barrier to good glycemic control.

The occurrence of severe sulfonylurea-induced hypoglycemia is minimized by avoiding sulfonylureas, particularly long-acting ones, in patients with predisposing conditions or who are taking potentially interacting drugs. When such cases do occur, the patients should be hospitalized. A bolus of 50% glucose should be given intravenously and should be followed by continuous infusion of 10% or 20% glucose. Blood glucose levels should be monitored for at least 3 days and maintained at $6-8\,\mathrm{mmol\,L^{-1}}$ ($110-145\,\mathrm{mg\,dL^{-1}}$). If intravenous glucose treatment is insufficient, hydrocortisone and/or glucagon administration may be useful. A somatostatin analogue (octreotide) has been shown to reverse sulfonylurea-induced hyperinsulinemia and hypoglycemia and has been shown to be very effective in severe or intractable cases of sulfonylurea-induced hypoglycemia [167–169].

Weight gain

Weight gain is a frequent complication of sulfonylurea treatment. The magnitude of weight gain differs among the different sulfonylureas and the particular clinical studies. Older, well-controlled studies found that the mean increase in body weight in patients with T2DM on sulfonylurea treatment was 2.8 kg [170]. This contrasted with the mean weight change ranging from −2.9 to +1.5 kg that occurred with comparable improvement in glycemic control by metformin treatment [170]. The UKPDS provides the best long-term data on body weight changes with sulfonylurea treatment. Glibenclamide treatment resulted in a mean 4 kg increase in body weight in the first 4 years of treatment [94] which then plateaued for the remaining 7 years of the study [91]. The diet-treated control patients had a mean 1 kg weight increase during the 11 years of the study. In contrast, metformin-treated patients had the same mean body weight increase as the diet-treated control patients and the insulin-treated patients had a progressive increase in body weight throughout the study achieving a body weight gain of 8 kg [91]. The ADOPT study carried out 20 years later confirmed that glibenclamide weight gain occurs in the first 1–2 years of treatment (1.6 kg) and then plateaus [101].

Epidemiologic data have shown that all-cause mortality is related to body mass index (BMI). The hazard ratios for all-cause mortality in overweight and obese diabetic patients relative to patients with BMI $18.5-25\,\mathrm{kg\,m^{-2}}$ are: overweight 0.97, type 1 obese (BMI $30-34.9\,\mathrm{kg\,m^{-2}}$) 1.13, and type 2 and 3 obese (BMI $\geq 35\,\mathrm{kg\,m^{-2}}$) 1.48 [171]. Voluntary weight loss has been demonstrated to decrease all-cause mortality. There are no specific data to prove that sulfonylurea-induced weight gain has detrimental effects on outcomes in patients with T2DM. There are several potential mechanisms that have been proposed to explain the weight gain associated with sulfonylurea treatment. Improvement in glycemic control decreases glycosuria and can increase caloric balance if food intake is

not sufficiently decreased. Many patients taking sulfonylureas have episodes of mild hypoglycemia that manifest themselves as hunger and contribute to excess calorie intake. There is some evidence that hyperinsulinemia itself may increase appetite.

Cardiovascular safety

The most frequently debated adverse effect of sulfonylureas is that of an alleged increase in cardiovascular mortality. This was initiated in 1970 by the University Group Diabetes Program (UGDP) report that subjects treated with tolbutamide had an increase in cardiovascular mortality compared to those treated with placebo [172]. After extensive analyses and debates carried out over several years, it seemed that these data might have been based on a spuriously low mortality rate in the placebo group [173]. However, subsequently several potential mechanisms have been elucidated which could account for sulfonylureas having detrimental effects during cardiac ischemia and the cardiovascular safety of sulfonylureas has continued to be an unresolved issue.

The discovery of K_{ATP} channels in the myocardium and vascular smooth muscle led to an understanding of their importance in the regulation of cardiac physiology. Myocardial ATP levels are ordinarily high because of the high rate of substrate oxidation. The K_{ATP} channels are therefore closed resulting in increased calcium ion entry into the myocardium and increased sarcolemma contraction. During myocardial ischemia, ATP levels fall causing the K_{ATP} channels to open. This results in decreased calcium entry into the myocardium, decreased energy expenditure, a reduction in action potential duration and an increase in re-entrant arrhythmias. Closure of the coronary artery smooth muscle cell K_{ATP} channel causes compensatory vasodilatation.

A transient episode of myocardial ischemia produces metabolic changes which protect the myocardium from the effects of a subsequent more prolonged episode of ischemia. This phenomenon is called ischemic pre-conditioning and reduces the myocardial damage caused by the prolonged ischemia [174,175]. It appears that ischemic preconditioning is related to opening of the cardiac mitochondrial K_{ATP} channel.

The SUR subunit of the myocardial K_{ATP} channel is the SUR2A isoform, that of the coronary artery is the SUR2B isoform, and that of the mitochondria is SUR1 but coupled to Kir6.1. Sulfonylurea drugs in the doses used clinically could close the myocardial, coronary artery smooth muscle cell and mitochondrial K_{ATP} channels and prevent the protective adaptation of the heart to anoxia and ischemia if they had sufficient affinities for the SUR2A, SUR2B, and Kir6.1 isoforms. The only sulfonylurea that has been shown to be capable of this in humans is glibenclamide. Ordinary pharmacologic doses of glibenclamide block ischemic preconditioning in both animal and human models of myocardial ischemia [139,140]. Other sulfonylureas such as glimepiride do not [139].

A second factor which could cause cardiac safety issues in diabetic patients taking sulfonylureas is effects of severe hypoglycemia on electrical impulse transmission in the myocardium leading to arrthymias. Several studies have shown that severe hypoglycemia leads to significant prolongation of the QT interval [176] which is known to predispose to arrthymias.

Whether these potential effects of sulfonylureas lead to increased myocardial damage and/or increased cardiovascular events can only be determined by clinical data or preferably controlled, clinical trials. After 40 years the data on sulfonylureas and cardiac safety are still controversial [177–181]. Retrospective analyses of several large databases report that chronic sulfonylurea treatment of patients with T2DM is associated with higher all-cause or cardiovascular mortality than patients in the database who were treated with metformin (Table 42.2). The issue of course is whether sulfonylureas increase cardiovascular mortality or metformin decreases cardiovascular mortality. Some of the studies summarized in Table 42.2 that compared the cardiovascular safety of the various sulfonylureas to each other show that glibenclamide is more detrimental to the heart than the other sulfonylureas. A study of the outcomes of 1310 diabetic patients included in the French Registry of acute myocardial infarctions in 2005 found that patients being treated with glibenclamide had an in-hospital mortality of 7.5% compared to one of 2.7% of those patients being treated with gliclazide or glimepiride [192]. In contrast, a meta-analysis of 21 studies from 1995–2005 reported that glibenclamide caused more hypoglycemia (83%) but the same rates of risk of cardiovascular events or death compared to other insulin secretagogues [193]. A retrospective cohort analysis using an academic health center enterprise-wide electronic health record of 11,141 patients with T2DM compared the risk of overall mortality of patients initiated on monotherapy with glyburide (4279), glipizide (4325), or glimepiride (2537) found a trend toward greater mortality of those in the glipizide (hazard ratio 1.39) and glyburide (hazard ratio 1.36) treated groups as compared to the glimepiride group [194].

In summarizing the large amount of data available, it does not appear that there is sufficient evidence to conclude that sulfonylureas in general cause an increase in cardiovascular events. Many of the studies were in diabetic populations with acute myocardial infarction or acute coronary syndrome so that detrimental effects of sulfonylureas on the cardiovascular system should have been evident. There continues to be concern, however, that glibenclamide in some subsets of patients may cause an increase in mortality. Since glibenclamide has never been shown to be more beneficial in controlling hyperglycemia than other sulfonylureas, and has a higher rate of severe hypoglycemia as well as possible detrimental cardiovascular effects, there is no rationale for its use as a therapeutic agent in T2DM. Metformin therapy seems to decrease cardiovascular events and mortality.

Table 42.2 Analyses of sulfonylurea effects on cardiovascular events and/or mortality in patients with type 2 diabetes

Sulfonylurea	Comparator	Number	Duration of follow-up	Results ratio (95% CI)	Ref.
Sulfonylureas	Metformin	5730	Up to 8 yrs	RR CV mortality 3.71 (2.64–5.22)	[182]
Sulfonylureas	Metformin	422 CHF	1 yr	RR all-cause mortality 1.69 (1.04–2.78)	[183]
Sulfonylureas	Metformin	98,665/155,025		Composite CVD events 1.21 (1.13–1.30)	[184]
Glyburide				1.26 (1.16–1.37)	
Glipizide				1.15 (1.06–1.25)	
Sulfonylurea	Metformin	3469/711 MI	2.2 yrs	HR composite CVD events	[185]
Glibenclamide				1.31 (1.17–1.46)	
Glimepiride				1.19 (1.06–1.32)	
Glipizide				1.25 (1.11–1.42)	
Tolbutamide				1.18 (1.03–1.34)	
Gliclazide				1.03 (0.88–1.22)	
Glipizide	Metformin	304 CAD Prospective study	5 yrs	HR composite CVD events 1.85 (1.11–3.33)	[186]
Sulfonylureas	Metformin	12,272	5.1 yrs	Sulfonylurea mortality 24.7% Metformin mortality 13.8%	[187]
First generation sulfonylurea	High/low dose	120	4.6 yrs	HR all-cause mortality 2.1 (1.0–4.7)	[188]
Glyburide		4138		1.3 (1.2–1.4)

Sulfonylureas as current therapeutic agents for type 2 diabetes

With the availability of many classes of agents to treat the hyperglycemia of patients with T2DM, it is important to examine the positive and negative aspects of sulfonylurea treatment for these patients. Sulfonylureas are glucose-independent insulin secretagogues, which means that their use will always be associated with a significant incidence of hypoglycemia with its potential moderate and severe clinical complications. Their use will lead to some weight gain, the clinical significance of which is unknown. The risks of an increase in cardiovascular events and cancer remain unclear. Long term, the lack of durability of glycemic effect and the possibility of detrimental effects on the β cell are major concerns.

Sulfonylureas have been shown to improve glycemic control when used as primary therapy in patients with T2DM inadequately controlled by lifestyle modification and when added as second- or third-line therapy to patients inadequately controlled with metformin, thiazolidinediones, insulin, and DPP-4 inhibitors. They have been used in combination with GLP-1 receptor agonists and SGLT-2 inhibitors. However, just as in first-line pharmacologic therapy, their use when combined with other agents is always accompanied by increased rates of moderate and severe hypoglycemia.

The question to be raised then is, are other strategies that are as effective and yet safer with less hypoglycemia and a potentially lower risk of CVD available to replace sulfonylureas? In this context, we turn to the insulin secretagogues which are glucose-dependent and cause little or no hypoglycemia. Obviously, the incretin-based therapies can provide such an alternative. Randomized, controlled clinical trials comparing sitagliptin to glipizide [195], saxagliptin to glipizide [196], and vildigliptin to glimepiride [197] in patients with

Table 42.3 Genetic variants of the pancreatic β-cell that are or may be specific targets for sulfonylurea treatment

1 Mutations of ABBC8 or KCNJ11 genes of the K_{ATP} channel that block the ability of ATP/ADP to regulate K_{ATP} channel closure and stimulate insulin secretion (neonatal diabetes mellitus) [204]. Ninety percent are able to be controlled on high doses of sulfonylureas rather than insulin [205].
2 HNF-1α mutations causing MODY-3 [202,203]. Five times more sensitive to sulfonylureas than metformin.
3 Mutations of KATP channel genes that are associated with some forms of T2DM [208]:
    (a) KCNJ11 Kir6.2 K23 variant is present in approximately 20 % of Caucasians with T2DM
    (b) K23 variant is associated with T2DM in almost all ethnic populations tested
    (c) K23 variant is closely coupled with SUR ABCC8 variant A1369
    (d) Haplotype A1369 ABCC8 and K23 KCNJ11 variant is responsible for increased risk for T2DM.
4 Polymorphisms of transcription factor 7-like 2 L (TCF-7L2) [206,207].

T2DM inadequately controlled on metformin treatment, have demonstrated that DPP-4 inhibitors are equally effective as sulfonylureas in decreasing HbA1c, yet cause no weight gain and are accompanied by rates of moderate hypoglycemia that are 10- to 15-fold lower than sulfonylureas and with almost no episodes of severe hypoglycemia. GLP-1 receptor agonists such as exenatide twice daily or once weekly as well as liraglutide are more potent in lowering glycemia than sulfonylureas or insulin, cause little or no hypoglycemia and are associated with weight loss [198–200]. While there are some concerns about incretin-based therapies being associated with an increased risk of acute pancreatitis and pancreatic cancer the current available data do not support such a concern [201]. The one clear advantage of sulfonylureas is their very low cost. One can then make the argument that DPP-4 inhibitors should be used preferentially to sulfonylureas in patients who are at increased risk of hypoglycemia from sulfonylureas. In patients in whom cost is critical, sulfonylureas are better than no therapy.

It is important, however, to recognize that sulfonylureas or meglitinides are the only agents that can close the pancreatic β-cell K_{ATP} channel when it is insensitive to closure by ATP/ADP. Such abnormalities are being recognized in individuals with abnormalities of genes for pancreatic β-cell ATP generation [202,203] or the subunits of the K_{ATP} channel [204,205]. Table 42.3 lists some of the known and potential abnormalities that can be uniquely benefitted by sulfonylurea therapy [202–208]. The glucose-dependent insulin secretagogues act through cyclic AMP and protein kinase A and do not act on the K_{ATP} channel.

Interactions

Several drugs interfere with the efficacy of sulfonylureas, by influencing their pharmacokinetics or pharmacodynamics, or both. As the majority of type 2 diabetes patients are elderly subjects or are in late middle age, they are liable to be exposed to other medication in addition to sulfonylurea. Thus, the risk of interactions is considerable. Two of the most important interactions may occur with alcohol and with aspirin, both of which may provoke, prolong, and/or deepen a hypoglycemic reaction [6,104,152]. Plausible and/or documented interactions are listed in Table 42.4. It should be noted that the degree and

Table 42.4 Mechanisms of drug interactions with sulfonylureas

Agents that augment sulfonylurea action and may cause profound hypoglycemia:
(A) Displacers of sulfonylureas from albumin binding sites
    (1) Aspirin and salicylic acid
    (2) Other nonsteroidal anti-inflammatory drugs
    (3) Sulfonamides
    (4) Trimethoprim
    (5) Fibrates
(B) Competitive inhibitors of sulfonylurea metabolism
    (1) Alcohol
    (2) H2-blockers
    (3) Sulfonamides
    (4) Anticoagulants
    (5) Pyrazolone derivatives (phenylbutazone, oxiphenbutazone, sulfinpyrazone)
    (6) Monoamine oxidase inhibitors
(C) Inhibitors of urinary excretion of sulfonylurea and active metabolites
    (1) Probenecid
    (2) Aspirin and salicylic acid
    (3) Other nonsteroidal anti-inflammatory drugs
    (4) Allopurinol
    (5) Sulfonamides
(D) Augmentors of the effect of sulfonylurea
    (1) Alcohol
    (2) Aspirin and salicylic acid
    (3) Guanethidine and betanidine
    (4) Monoamine oxidase inhibitors
(E) Antagonists of endogenous hyperglycemic hormones
    (1) B-Blockers
    (2) Sympatholytic drugs

Agents that attenuate sulfonylurea action and may counteract the antihyperglycemic effect:
(A) Enzyme inducers that increase sulfonylurea elimination
    (1) Alcohol (chronic, moderate use)
    (2) Barbiturates (chronic, moderate use)
    (3) Rifampicin
(B) Agents that antagonize sulfonylurea action
    (1) B-Blockers
(C) Inhibitors of insulin secretion or insulin action
    (1) Thiazides and loop diuretics
    (2) Diazoxide
    (3) B-Blockers
    (4) Phenytoin
    (5) Corticosteroids
    (6) Estrogens
    (7) Indomethacin
    (8) Isoniazid
    (9) Nicotinic acid
(D) Mechanism obscure
    (1) Phenothiazines
    (2) Acetazolamide

extent of a certain interaction may vary between the different sulfonylureas.

Toxicity

Most idiosyncratic toxic effects of sulfonylureas are said to appear within the first 2 months of treatment. They include the following:

Blood: Agranulocytosis, thrombocytopenia, bone marrow aplasia, red cell aplasia, hemolytic anemia

Skin: Rashes, pruritus, erythema nodosum, erythema multiforme, Stevens–Johnson syndrome, exfoliative dermatitis, purpura, photosensitivity

Gastrointestinal tract: Nausea, vomiting, heartburn

Liver: Abnormal function tests, jaundice, cholestasis, granulomatous hepatitis

Lung: Possible diffuse pulmonary reaction

Thyroid: Weak antithyroid activity

Kidney: Antidiuresis, water retention (chlorpropamide)

Vasomoto: Alcohol flush, tachycardia, headache (mainly chlorpropamide)

Cardiovascular: Vasculitis

Contraindications

The following patients should not be treated with sulfonylureas:

1 patients with type 1 diabetes or "pancreatic" diabetes
2 pregnant women (only glyburide treatment is acceptable)
3 patients with severe infections, stress, or trauma
4 patients with a history of severe adverse reactions to sulfonylureas
5 patients particularly prone to develop hypoglycemia, e.g. with liver or kidney disease.

Conclusion

Sulfonylureas and meglitinides are a class of glucose-independent insulin secretagogues which act by closing the pancreatic β-cell plasma membrane K_{ATP} channel. They are effective in improving glycemic control in patients with T2DM who are inadequately controlled on lifestyle modification. They are effective in mild to moderately hyperglycemic patients who still have modest pancreatic insulin reserve. They improve fasting plasma insulin levels. They do not correct the defect in the delay in early meal-mediated insulin secretion but increase late meal-mediated insulin secretion. Their effect on glycemic control has limited durability. Hypoglycemia is the major side effect and it can be the cause of significant morbidity and mortality. Modest weight gain occurs with sulfonylurea therapy. Cardiovascular safety during sulfonylurea therapy continues to be an unanswered question.

While the different sulfonylureas may have different intrinsic activity due to their binding characteristics for the K_{ATP} channel, the clinical benefits are the same when the appropriate dose is prescribed. Differences in hypoglycemia, dosing and duration of effects are due to differences in rates of absorption, plasma half-life, modes of metabolism, and methods of excretion.

Glucose-dependent insulin secretagogues are as or more effective in controlling glycemia and do not have the weight gain or hypoglycemia associated with sulfonylurea therapy. However, sulfonylureas are unique in being able to ameliorate the inability of the ATP/ADP ratio to facilitate insulin secretion and are the treatment of choice for such disturbances.

Metformin and other biguanides: pharmacology and therapeutic usage

Susan L. Samson and Alan J. Garber

Department of Medicine, Baylor College of Medicine, Houston, TX, USA

Key points

- Metformin is a first-line oral therapy for type 2 diabetes mellitus and is available in long-acting form and in combination formulations with other oral diabetes medications.

- The structure of metformin is N^1,N^1-dimethyl biguanide, a derivative of guanidine.

- Metformin inhibits mitochondrial complex I resulting in altered AMP/ATP ratios in the cell. One consequence is activation of AMP-activated protein kinase which has pleiotropic effects on lipid and glucose metabolism.

- Metformin improves glycemic control mainly through inhibition of hepatic gluconeogenesis, and there also are improvements in peripheral glucose uptake and lipid metabolism.

- Metformin has positive effects in other metabolism-related diseases including polycystic ovary syndrome, nonalcoholic fatty liver disease, and HIV lipodystrophy.

- A common side effect is gastrointestinal upset which is usually self-limiting and rarely causes discontinuation of the medication.

- Although the risk of lactic acidosis with phenformin was significant, the risk of lactic acidosis with metformin approaches zero within appropriate prescribing practices.

Introduction

Metformin is the first-line therapy in the pharmacologic treatment of type 2 diabetes mellitus (T2DM), both as monotherapy and in combination with other medications. There are 40–50 years of experience with metformin in Canada and Europe, with a more recent introduction to the US market in 1995. The chemical structure of metformin is related to guanidine (Figure 43.1). The glucose-lowering properties of guanidine derivatives were recognized through the study of French lilac (*Galega officinalis*, also known as Italian fitch, goat's rue, Spanish sainfoin, professor-weed, and false indigo),

which was used as a remedy for symptoms of glucosuria as early as medieval Europe (Figure 43.2). The high isoamylene guanidine (galegine) content of *G. officinalis* was responsible for the hypoglycemic properties of this perennial herb [1].

Extracts from *G. officinalis* were used to treat diabetes in the 1920s but had prohibitive gastrointestinal side effects [1]. The diguanides (two guanidine molecules connected by a carbon chain, Figure 43.1) were synthesized in the 1920s, but were hepatotoxic [1]. Biguanides (two linked guanidine molecules minus an ammonia radical) were synthesized in the 1950s and of the 300 or so biguanides synthesized, three have glucose-lowering properties: phenformin, buformin, and metformin. These drugs were used to treat diabetes for nearly 20 years but phenformin and buformin were withdrawn from the market in most countries by 1978 because of an association with fatal lactic acidosis [2]. Metformin has a very low rate of lactic acidosis compared with phenformin but was guilty by association. Additionally, in the late 1970s, the University Group Diabetes Program trial reported an increased risk for cardiovascular mortality with the prolonged use of oral hypoglycemic agents, including phenformin, compared with the use of insulin [3]. Although flaws in the design and conclusions of the trial later emerged, these events precluded the approval of metformin in the United States for nearly two decades.

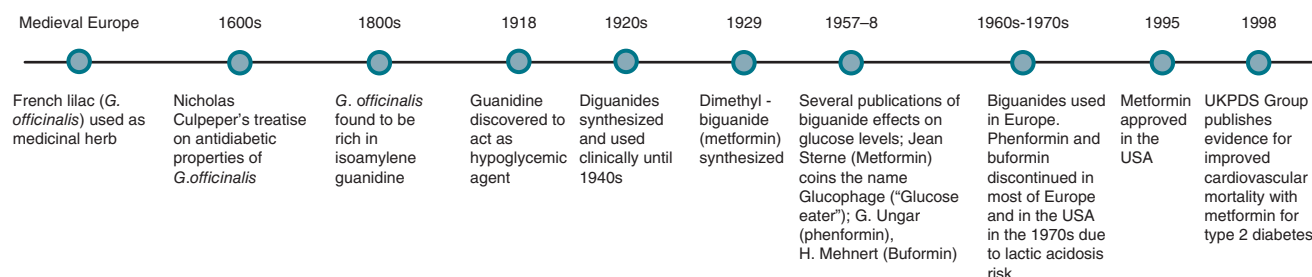
Resurgence of interest in metformin occurred in the 1980s and 1990s based on clinical studies demonstrating its efficacy and safety in T2DM, especially with publication of the United Kingdom Prospective Diabetes Study (UKPDS) [4]. Metformin was shown to have efficacy similar to that of sulfonylureas in reducing fasting plasma glucose (FPG) and postprandial glucose concentrations, but did not cause weight gain or hypoglycemia in contrast to sulfonylurea therapy [4,5]. Pursuant to the UKPDS findings, and subsequent favorable recommendations regarding its use, metformin is the most commonly used diabetes drug throughout the world.
Figure 43.1 Chemical structures of guanidine derivatives used to treat hyperglycemia. The nonpolar hydrocarbon side chain of the biguanides (highlighted area) determines the degree of lipophilicity of the molecule and binding to the membrane.


Figure 43.2 Historical timeline of diabetes treatment with guanidine derivatives.

Pharmacology

The unique hydrocarbon side chains of the biguanides (Figure 43.1) determine their lipophilicity and membrane binding affinity. The phenformin side chain contains a phenyl group, enabling it to permeate membranes including those of mitochondria. Metformin has a methyl side chain and exists as a hydrophilic cation or base at physiologic pH, precluding passive diffusion through cell membranes [6]. As a result, uptake of metformin into cells depends on organic cation transporters (OCT) of the *SLC22A* gene family. Metformin is absorbed in the intestine mediated by the plasma membrane monoamine transporter (PMAT), and perhaps aided by OCT3 on the luminal side of the enterocyte [7]. OCT1 and OCT3 proteins aid in the transport of metformin into the interstitial fluid on the basolateral side, and also are involved in uptake by the liver, skeletal muscle, and heart [6,7]. Metformin does not bind plasma proteins and is filtered unhampered at the glomerulus where renal tubule cells take up metformin mainly via OCT2 [6]. Unmodified metformin is excreted by the kidney by active tubular secretion mediated by the human multidrug and toxin extrusion 1 protein (MATE1), as well as MATE2K and OCT1 [6,7]. The pharmacokinetics of metformin varies among individuals explaining the variability seen in the glycemic responses to metformin. This may in part be due to genetic polymorphisms altering expression and/or function of the metformin transporters which alter absorption or renal clearance [6,7]. Cationic drugs, such as cimetidine, requiring the same transporters as metformin in the kidney can alter metformin clearance [6].

Mechanism of action

Mitochondrial respiration and AMP-activated protein kinase

Metformin has pleiotropic effects on glucose and lipid metabolism in clinical studies and researchers have begun to unravel the underlying mechanisms (Figure 43.3). Guanidine was reported to decrease mitochondrial oxidative phosphorylation in the 1950s [8]. Similarly, metformin has been demonstrated to inhibit complex I of the mitochondrial respiratory chain [9,10]. In simple terms, this would decrease entry of NADH into the respiratory chain and lower the proton motive force, decreasing ATP synthesis at complex V, increasing relative levels of AMP (Figure 43.3). Overall, the cell would perceive that there is an energy deficit and engage in metabolic processes to relieve that stress. Related to this, a key finding in the last decade or so is that metformin activates AMP-activated protein kinase (AMPK) [11].

AMPK is the energy sensor of the cell by detecting changes in the ratio of AMP or ADP to ATP. AMP binds the regulatory γ subunit to allosterically activate AMPK and promote phosphorylation at Threonine 172 (Thr172) of the catalytic α subunit [12]. AMP binding also protects AMPK dephosphorylation by cell phosphatases. AMPK phosphorylates key enzymes and transcription regulators [13]. The net effect is the downregulation of energy-consuming, anabolic processes, such as gluconeogenesis and lipid synthesis, along with activation of ATP-generating catabolic processes, such as fat oxidation (Figure 43.3). A key upstream AMPK kinase known to modify Thr172 is the Peutz-Jegher tumor-suppressor gene product (LKB1) [12].
Figure 43.3 Schematic diagram of the biochemical effects of metformin in different cell types. Metformin inhibits mitochondrial complex I, reducing ATP production and increasing the AMP/ATP ratio in the cell. In the hepatocyte, AMP decreases the activity of fructose-1,6-bisphosphatase and the reduced ATP decreases the activity of pyruvate kinase to reduce gluconeogenesis. Additionally, the increased AMP/ATP ratios activate AMP-activated protein kinase (AMPK) which inhibits gluconeogenic gene expression. In the adipocyte, AMPK activation decreases hormone sensitive lipase activity, reducing lipolysis. Additionally, acetyl CoA carboxylases (ACC) 1 and 2 are inactivated by AMPK, resulting in decreased malonyl CoA production and increased transfer of fatty acids into the mitochondria via carnitine palmitoyltransferase (CPT). The net result is decreased fatty acid synthesis and increased beta oxidation. In skeletal muscle, AMPK increases glucose transporters at the plasma membrane to augment glucose uptake.

Although AMPK is thought to be a central player in the actions of metformin, the pathway from metformin to AMPK is not fully elucidated. Shaw et al. [14] demonstrated that loss of the upstream kinase LKB1 abrogated AMPK activation and the glucose lowering effects of metformin *in vivo* in a mouse knockout model. Thus, the downstream activation of AMPK by LKB1 appeared independent of fluctuations in cellular ATP content. However, the absolute requirement for LKB1 has been questioned by experiments demonstrating that metformin can dampen hepatocyte gluconeogenesis in the absence of LKB1, and even AMPK [15,16], due to a decrease in cellular energy state [15,16]. This comes full circle to an early hypothesis of metformin-induced mitochondrial complex I inhibition causing increased AMP/ATP ratios in the cell. AMP binds AMPK, which permits activation by upstream kinases including LKB1, although whether this is completely an "off target" or passive event is not clear. There is no evidence of direct activation of LKB1 or AMPK by metformin in cell-free experiments [17]. Obviously, there is still further research to be done in this exciting field.

Gluconeogenesis

Hepatic glucose output is inappropriately high in patients with T2DM, contributing to hyperglycemia. The ability of the biguanides to decrease hepatic gluconeogenesis was reported in a letter to *Nature* in 1967 [18], and metformin reduces glucose production 25–40% in human subjects [19,20].

There is evidence that metformin-induced AMPK activation is partially responsible for the downregulation of gluconeogenesis [12]. Glucose-6-phosphatase (G6Pase) and phosphoenolpyruvate carboxykinase (PEPCK) are the rate-limiting enzymes of gluconeogenesis and a significant point of their regulation is at the level of gene transcription. There are several means by which metformin has been shown to affect G6Pase and PEPCK expression, mediated by AMPK [13]. The CREB (cAMP-responsive element binding protein) transcription complex binds to the regulatory regions of the PEPCK and G6Pase genes to increase their expression. CREB also regulates transcription of peroxisome proliferator-activated receptor-γ co-activator 1α (PGC-1α) which is an active participant in the transcription of G6Pase and PEPCK [21]. AMPK phosphorylates a component of the complex, CREB-regulated transcription co-activator 2 (CRTC2), excluding it from the nucleus [14]. AMPK also activates the nutrient sensor sirtuin 1 (sirt1) which deacetylates CRTC2 to promote its degradation [22]. The CREB complex also can be disassociated by phosphorylation of CREB binding protein (CBP) by atypical protein kinase C, a target of AMPK [23]. Finally, expression of the orphan nuclear receptor small heterodimer partner (SHP) is increased in cultured cells by metformin treatment in an AMPK-dependent manner, and SHP directly interacts with CREB as well as PGC-1α to disrupt gluconeogenic gene transcription [24].

In spite of the importance of G6Pase and PEPCK expression in the global regulation of gluconeogenesis, changes in transcription rates are not a means to respond to metabolic needs on a minute-by-minute basis. Recent experiments have shown that metformin can alter the rate of gluconeogenesis independent of changes in enzyme expression [15]. At the midpoint of the gluconeogenic pathway, fructose-1,6-bisphosphatase is allosterically inhibited by AMP, decreasing conversion from fructose-1,6-bisphosphate to fructose-6-phosphate, a precursor to the synthesis of glucose [25]. Additionally, pyruvate kinase also provides a key point of regulation by energy charge as it is allosterically inhibited by ATP [26]. A drop in the cellular ATP content, such as caused by metformin, promotes pyruvate kinase activity, removing phosphoenolpyruvate from the gluconeogenic pathway because of its conversion to pyruvate. Therefore, a decrease in cellular energy charge caused by metformin could be the basis for acute changes in gluconeogenesis, with additional longer term effects involving downregulation of gluconeogenic enzyme expression as mediated by AMPK.

Peripheral glucose uptake

Although gluconeogenesis is recognized as the major metabolic process affected by metformin, clinical data show that metformin increases insulin-mediated whole-body glucose uptake [27] and glucose utilization 20–50% [28,29]. Skeletal muscle is responsible for approximately 80% of glucose uptake and utilization, so improvements in glucose disposal are expected to involve this important metabolic tissue. Euglycemic-hyperinsulinemic clamp studies in human subjects have been divided on the evidence for [29–32] and against [27,28,33,34] improved peripheral insulin sensitivity with metformin, perhaps due to subtle methodological differences.

In vitro studies have demonstrated that metformin can increase glucose uptake into muscle cells using rodent and human cell lines, primary culture, and isolated muscle tissue [35–39]. The rate of glucose uptake in skeletal muscle is dependent on facilitated diffusion via glucose transporters (GLUT) in the plasma membrane (PM). Insulin signaling induces GLUT4 translocation to the PM, while GLUT1 is already present in the PM at basal levels. From the experimental data, the observed increases in glucose uptake appear to be independent of, and additive to insulin treatment with the exception of one study [35]. On its own, metformin increases PM-associated levels of GLUT1 [40] and GLUT4 [41] in L6 myotubes. Notably, most *in vitro* experiments have been performed with what are supratherapeutic levels of metformin ($\sim$1–2 mmol L^{-1}), which would not be achieved with *in vivo* treatment with metformin (μmol L^{-1} range), so caution is required in extrapolating these results to the clinical realm [42].

AMPK also may be central to the above observations since AMPK activation increases GLUT4 transcription and translocation [43,44] and contributes to metformin-induced GLUT4 translocation in muscle cell lines [37,41]. Reductions in GLUT4 endocytosis with chronic insulin stimulation also are mediated by AMPK in cardiomyocytes [45] and adipocytes [46].

Importantly, metformin has been shown to activate AMPK *in vivo* in human subjects with T2DM in both muscle [47] and adipose tissue [48], so that these *in vitro* observations may be relevant to the clinic.

Lipid metabolism

Metformin has well-documented favorable effects on serum lipid and lipoprotein parameters [49], with the most pronounced effect on serum triglycerides. *In vivo*, treatment of subjects with T2DM for 10 weeks with metformin versus a sulfonylurea results in increased phosphorylation of AMPK in adipose tissue biopsies [48]. In human primary adipocytes, metformin (at $2\,mmol\,L^{-1}$) inhibits β-adrenergic stimulation of lypolysis, dependent on AMPK [50]. Importantly, AMPK directly phosphorylates hormone-sensitive lipase, attenuating its activation by protein kinase A, decreasing lipolysis [48]. *In vivo*, this would decrease the amount of circulating free fatty acids (FFA), with less taken up by the liver, reducing hepatic secretion of very low-density lipoprotein (VLDL), and therefore hypertriglyceridemia [28,51].

Metformin also affects the interplay between fatty acid synthesis and β-oxidation through AMPK activation. AMPK phosphorylates and inactivates the acetyl CoA carboxylases (ACC) 1 and 2. The consequence is a decrease in malonyl CoA levels which discourages fatty acid synthesis while releasing carnitine palmitoyl transferase 1 (CPT1) from inhibition to facilitate entry of fatty acids into the mitochondria for β-oxidation [13,52]. The increased phosphorylation and inhibition of ACC by metformin has been reported in adipocytes [53], human adipose tissue [48], muscle [47], and liver [11]. It could seem paradoxical that a molecule implicated in inhibition of mitochondrial respiration would favor fatty acid oxidation. However, inhibition of complex I by metformin *in vitro* is rapidly reversed in the presence of high concentrations of FFA, promoting their β-oxidation [53]. AMPK also inhibits the transcriptional activity of sterol regulatory element-binding protein-1c (SREBP-1c), which regulates the expression of enzymes involved in *de novo* fatty acid synthesis, including fatty acid synthase [54]. Decreased synthesis and increased oxidation of fatty acids in the hepatocyte could be an explanation for decreased triglyceride storage in the liver seen with metformin treatment in animal models of obesity as well as some human studies [55,56].

Treatment of type 2 diabetes mellitus

Type 2 diabetes is a complex, slowly evolving metabolic disorder characterized by (1) impaired glucose uptake and utilization in peripheral tissues due to insulin resistance, (2) inappropriately increased hepatic glucose output, and (3) impaired β-cell insulin secretion. With regard to the latter defect, metformin does not increase insulin secretion and does not cause hypoglycemia [27]. Consequently, metformin is more accurately described as an antihyperglycemic agent rather than an oral hypoglycemic agent. The clinical efficacy of metformin has been well established through many well-controlled clinical trials with sample sizes ranging from several hundred to several thousand patients. For brevity in this chapter, we are unable to give well-deserved citations for each and every trial that has provided important evidence on the efficacy of metformin.

Glycemic control

Metformin is the first-line pharmacologic treatment for patients with T2DM, supported by consensus statements by several professional diabetes associations throughout the world [57,58]. In early clinical trials, metformin monotherapy reduced fasting plasma glucose by approximately $50\text{--}90\,mg\,dL^{-1}$ $(3\text{--}5\,mmol\,L^{-1})$ and A1c by 1.4–2.0% over a dose range of 1700 mg to 3000 mg daily [29,59,60]. Reductions in glycemic parameters are log-linear and dose-dependent allowing for incremental titration to effect [59]. Metformin is as effective as sulfonylureas or insulin in reducing FPG and A1c levels in patients with T2DM, but unlike sulfonylureas, fasting and postprandial serum insulin concentrations are unchanged or decreased with metformin [61,62]. Table 43.1 summarizes the accumulated metabolic data regarding metformin therapy derived from placebo- and active-controlled clinical trials in adults.

Product formulations

Metformin is available in immediate release (IR) and extended release (XR) tablets (Table 43.2). XR is equally efficacious in reducing A1c, fasting plasma glucose and postprandial glucose concentrations [63] and patients switched from IR to XR maintain comparable glycemic control. In healthy volunteers, maximum plasma concentrations achieved after a 2000 mg evening dose of XR are approximately 36% higher than following a 1000 mg evening dose of the IR formulation given twice daily [64]. Time to peak concentration is reached later (median, 7 h) with XR than with IR (approximately 2–3 h), but the extent of absorption, as measured by area-under-the-curve (AUC) of concentration by time, is similar between the formulations [64,65].

XR offers the advantage of once-daily administration at any dose and appears to have a better gastrointestinal tolerability profile [63]. Gastrointestinal adverse events were reported by 29% of patients receiving XR 1000 mg and by 39% of patients receiving IR 500 mg twice daily [66]. XR tablets contain a dual hydrophilic polymer matrix system which releases the drug slowly after ingestion. Fluid from the gastrointestinal tract enters the tablet and causes the polymers in the tablet to hydrate and swell [66]. Metformin is released through the process of diffusion and metered out over the dosing period. This process is independent of the pH of the gastrointestinal fluid and agitation.

In patients not achieving glycemic goals with metformin monotherapy, the addition of a second diabetes agent can produce significant and additive reductions in A1c and FPG. Also, with the multiple metabolic defects in T2DM, other agents

Table 43.1 Clinical effects of metformin

Parameter	Effect
Glycemic control versus placebo	Fasting plasma glucose reduced by $3-5$ mmol L^{-1} ($52-92$ mg dL^{-1})
	A1c reduced $1.4-2.0\%$
	Basic metabolic glucose clearance increased $30-53\%$
All-cause mortality	Reduced 36% compared to insulin or sulfonylurea therapy in overweight patients
Stroke	Reduced 36% compared to insulin or sulfonylurea therapy in overweight patients
Serum triglycerides	Reduced $15-45\%$ dependent on baseline level
High-density lipoproteins cholesterol (HDL)	Unchanged or slightly increased
Low-density lipoproteins cholesterol (LDL)	Reduced $5-10\%$
Body weight	Variable with no loss reported in some studies, but other studies show loss in range of 0.7 kg to 5 kg with greater loss in heavier patients
Fibrinolysis	Reduces PAI-1 and tPA levels

can complement metformin, targeting additional physiologic defects. Combination of a second oral diabetes medication with metformin in the same tablet allows for simplified dosage regimens, particularly attractive among a population of patients that may have other comorbidities and require multiple medications. Metformin is available combined with glinides, sulfonylureas, thiazoladinediones, and dipeptidyl peptidase 4 inhibitors (Table 43.2). These agents will further lower the A1c (-0.64% to -0.97%) when added to metformin therapy [67]. The majority of combinations of these drugs with metformin are proven bioequivalent when administered in separate tablets or together in a single tablet. The combination glyburide/metformin is actually superior in clinical efficacy compared to equivalent doses given alone. In a randomized, double-blind crossover study, 2-h postprandial glucose excursion was significantly lower on day 14 after a mixed meal with the combination tablet than when given as the individual drugs [68]. The combination tablet has controlled particle sizes of glyburide, ranging from 6 to 21 µm so there is rapid release of glyburide at $2-3$ hours, followed by a secondary peak $5-6$ hours post dose [69]. In contrast, glyburide tablets administered separately with metformin tablets produce a single peak and twofold lower glyburide delivery in the first 3 hours [68].

The addition of metformin to insulin therapy in patients with T2DM further improves fasting glucose and A1c and can reduce insulin needs by approximately $25-36\%$ in some studies, and in some cases obviating the need for insulin completely in other studies [70,71]. Additionally, when added to insulin therapy, metformin therapy does not induce hypoglycemia and can even promote weight loss [70,71].

Microvascular and macrovascular risk reduction

The efficacy of metformin in improving glycemic control and reducing microvascular complications of diabetes is similar to that of other oral agents used for the treatment of diabetes, related to A1c lowering [72]. The potential of metformin monotherapy to reduce adverse macrovascular endpoints in overweight T2DM patients first emerged in the UKPDS, which was undertaken to determine the long-term effects of improved glycemic control on complications of T2DM [5]. The study enrolled 4075 patients with newly diagnosed T2DM who were randomly assigned to receive either "conventional therapy," which was mainly dietary with a goal fasting glucose of less than 15 mmol L^{-1} (270 mg dL^{-1}), or "intensive therapy" which involved active treatment with sulfonylurea, insulin, or metformin with a target fasting glucose of less than 6 mmol L^{-1} (108 mg dL^{-1}). Over a mean of 10 years of follow-up, the treated patients had a median A1c of 7.0% compared with 7.9% in the conventional group [4]. The improvement in glycemic control with drug therapy was associated with a 12% risk reduction for any diabetes-related endpoint and a 25% risk reduction for microvascular complications compared to conventional therapy. It was more difficult to tease out the impact of diabetes treatment on macrovascular complications. However, a greater than expected benefit was seen for overweight patients on metformin. Although a somewhat smaller A1c difference was achieved on metformin therapy, there were significant reductions in risk for all-cause mortality and stroke versus intensive therapy with sulfonylureas or insulin [72]. A combined analysis of the main and supplementary UKPDS studies found a 19% reduction in risk in diabetes-related endpoints with metformin ($p = 0.03$). To date, metformin is the only antidiabetic agent to show an independent benefit on the macrovascular complications of diabetes, by reducing the risk for myocardial infarction. A supplemental study detracted from the positive findings with metformin because of data which showed a significant increase in diabetes-related and all-cause deaths with early addition of metformin to ongoing sulfonylurea therapy [72,73]. However, there were a small number of endpoints in the two groups ($n = 269$, 268), and additional epidemiologic analysis of the data did not confirm the negative effect of combined metformin and sulfonylurea therapy. Although the interpretation of cardiovascular data drawn from the UKPDS has been debated, additional smaller trials (cohort and randomized controlled)

Table 43.2 Metformin[a,b] product formulations

Active ingredient(s)	Formulation	Strength (mg)	Dosing	Maximum daily dose (mg)
Metformin HCl	Immediate-release tablet	500, 850, 1000	500 or 850 mg three times per day with meals or ≤2000 mg d^{-1} can be given twice per day with meals	2550
	Extended-release tablet	500, 750	Once per day with evening meal	2000
	Liquid	100 mg mL^{-1}	Twice per day with meals	2000
Dipeptidyl peptidase IV inhibitor with metformin HCl	Sitagliptin/metformin tablet	50/500 50/1000	Twice per day with meals	100/2000
	Sitagliptin/metformin extended-release tablet	50/500 50/1000 100/1000	Once per day with evening meal	100/2000
	Linagliptin/metformin tablet	2.5/500 2.5/850 2.5/1000	Twice per day with meals	5/2000
	Saxagliptin/metformin[c] extended release tablet	2.5/1000 5/500 5/1000	Once per day with evening meal	5/2000
	Alogliptin/metformin	12.5/500 12.5/1000	Twice per day with meals	25/2000
	Vildigliptin/metformin	50/500 50/850 50/1000	Twice per day with meals	100/2000
Insulin secretagogue with metformin HCl	Glyburide/metformin tablet	1.25/250 2.5/500 5/500	Twice per day with meals	20/2000
	Glipizide/metformin tablet	2.5/250 2.5/500 5/1000	Twice per day with meals	20/2000
	Repaglinide/metformin tablet	1/500 2/500	Twice per day with meals	4/2000
Thiazoladine-dione with metformin HCl	Pioglitazone[d,e]/ metformin tablet	15/500 15/850	Twice or three times per day with meals	45/2550
	Pioglitazone[d,e]/ metformin extended release tablet	15/1000 30/1000	Once per day with evening meal	45/2000
	Rosiglitazone[d,f]/ Metformin tablet	2/500 4/500	Twice per day with meals	8/2000
	Rosiglitazone[d,f]/ Metformin extended release tablet	2/1000 4/1000	Once per day with evening meal	8/2000

[a]Metformin should not be used in patients with a serum creatinine ≥1.5 mg dL^{-1} (≥136 mmol L^{-1}) in men and ≥1.4 mg dL^{-1} (≥124 mmol L^{-1}) in women (USA) or creatinine clearance <60 mL min^{-1} (Canada).

[b]Avoid in liver disease which is a risk factor for lactic acidosis.

[c]Maximum 2.5/1000 daily if on a Cyp3A4/5 inhibitor.

[d]Do not initiate with active liver disease or alanine transferase levels >2.5 times the upper limit of normal (ULN). Discontinue if alanine transferase levels remain >3 times the ULN or patient is jaundiced.

[e]Maximum 15 mg pioglitazone daily if on a strong Cyp2C8 inhibitor.

[f]Patients on rosiglitazone must be registered with the patient access program (USA) and sign informed consent (Canada).

also have reported a decrease in macrovascular complications with metformin [74–76].

The effects of metformin on macrovascular outcomes could be independent of glucose-lowering and the result of the influence of metformin on multiple cardiovascular risk factors [77], including serum lipid and lipoprotein parameters (Table 43.1), although the most pronounced effects are reductions in serum triglycerides [60,78]. Possible mechanisms are the decreased synthesis of very low-density lipoprotein (VLDL) particles, which are lowered with metformin therapy, inhibition of hepatic VLDL secretion, and increased clearance of chylomicrons [28,51,79]. Total and LDL-cholesterol concentrations are also reduced, although to a lesser extent. HDL-cholesterol concentrations are usually unchanged or slightly increased with metformin therapy.

Insulin resistance is accompanied by endothelial dysfunction, with pathologic disturbances of vasoregulatory and thrombosis-related substances secreted by endothelial cells. Plasminogen activator inhibitor 1 (PAI-1), which inhibits tissue plasminogen activator (tPA) and fibrinolysis, is elevated in insulin-resistant states. Using human adipose tissue *in vitro*, metformin $(0.1–10\,\mu M)$ decreases PAI-1 expression in a dose-dependent manner [80]. Clinically, metformin therapy reduces PAI-1 concentrations approximately 20% and the fibrinolytic response is enhanced [81,82]. Levels of tPA also are significantly reduced with metformin therapy [83,84].

Overall, metformin improves serum lipoprotein parameters, reduces body weight, and stimulates fibrinolysis, factors that potentially could result in reduced adverse macrovascular outcomes exclusive to metformin compared with other diabetes treatments. Further research is warranted to understand the true value and underlying mechanisms for metformin effects on cardiovascular health.

Additional therapeutic potential

Diabetes prevention

The Diabetes Prevention Program assessed whether intensive lifestyle modification or metformin therapy prevented or delayed the onset of T2DM in at-risk patients with impaired glucose tolerance (IGT) [85]. Over the 2.8 year study, the incidence of diabetes was reduced 58% with intensive lifestyle modification and 31% with metformin treatment compared with the placebo treatment [85]. There were no differences in outcomes by sex or ethnic group, but metformin was most effective in patients younger than 60 years of age and in individuals with higher body mass index $(>35\,kg\,m^{-2})$ and higher baseline FPG [85]. Metformin therapy led to improvements in indices of insulin sensitivity and caused weight loss, which explained more than half of the effect on diabetes risk [86].

The Diabetes Prevention Program Outcomes Study (DPPOS) is an open-label extension of the DPP. The incidence of diabetes with metformin and lifestyle continued to be reduced compared to placebo up to 10 years after the original DPP randomization, but the metformin group had the lowest A1c and fasting glucose [87]. Reversion to normoglycemia just once during the DPP intervention, measured by FPG or glucose tolerance testing, reduced the risk of developing diabetes by more than 50% in the DPPOS extension [88], emphasizing the impact of early intervention in the prediabetic phase. Adherence was not the only factor affecting the response to metformin. Genetic analysis of the DPP metformin cohort revealed that the strongest genetic association with progression to diabetes was with polymorphisms in the AMPK γ subunit gene *PRKAG2*, with minor contributions by variations in the genes for the α1 and α2 subunits [89]. There also was an association with polymorphisms in cation transporters that mediate metformin transport into cells [89].

Metformin also has been shown to prevent progression to diabetes in patients with IGT in studies from India (−26%) and China (−77%) [90,91]. Metformin also prevents progression to diabetes by 50% in women with a history of gestational diabetes (GDM), compared to women with the same baseline glucose intolerance but without a history of GDM during pregnancy [92]. In spite of the data supporting the benefits of metformin for diabetes prevention, it currently is not approved by the U.S. Food and Drug Administration for diabetes prevention. Nor is it explicitly endorsed by guidelines from professional diabetes organizations at this time.

Diabetes in pregnancy

Tight glycemic control is warranted during pregnancy to reduce the risk for congenital abnormalities [93]. Metformin is afforded a pregnancy category B (FDA) rating with no evidence of teratogenicity in animal studies, but insufficient evidence of safety in human pregnancy. Transporters are present on the placenta facilitating exposure of the fetus to metformin [6]. Metformin is found in breast milk delivering less than 1% of the mother's dose based on weight and does not cause hypoglycemia in the infant [93].

At this juncture, professional organizations do not explicitly endorse the use of metformin during pregnancy. However, there is data to support its use. In a large randomized trial, women with gestational diabetes were randomized to metformin or insulin [94]. Metformin use did not have adverse effects on neonatal outcomes, including prematurity and birth weight. Only 2% of subjects discontinued metformin due to gastrointestinal symptoms, and metformin was preferred compared to insulin, which caused a higher rate of severe hypoglycemia.

Weight loss

Metformin has been shown to reduce body weight independent of dosage. The mean weight loss is in the range of 1 to 5 kg, or a 1 to 3% reduction from baseline, reported in clinical trials in both diabetic patients and nondiabetic individuals [5,27]. Weight loss is greatest in the most obese patients [27] and is durable for at least 10 years in adherent patients from the

DPPOS [95]. Metformin also helps to counteract the weight gain caused by other oral agents including insulin, sulfonylureas, and thiazolidinediones [4,96]. Significant weight loss with metformin also has been achieved in women with polycystic ovary syndrome [97], patients with HIV lipodystrophy [98], and patients treated with weight-promoting antipsychotic and mood-stabilizing drugs [99]. Currently, weight loss is not an approved indication for use of metformin out of the context of treatment for diabetes.

Polycystic ovary syndrome

Polycystic ovary syndrome (PCOS) is a common endocrine disorder occurring among women of reproductive age and is the predominant cause of chronic anovulation and infertility.

The 2003 Rotterdam consensus broadened the diagnostic criteria of PCOS from the 1990 NIH consensus to include two of three of the following: (1) oligo- or amenorrhea, (2) clinical or biochemical signs of hyperandrogenism, and (3) polycystic ovaries by ultrasound [100]. Notably, being overweight or obese is not part of the criteria, but the prevalence of obesity in this population ranges from a low of 10% to 60–80%, dependent on ethnic background [100]. Insulin resistance is present in 70% of PCOS patients [101] and is compensated by hyperinsulinemia which has a central role in the pathogenesis of PCOS [102].

There is an insulin-induced increase in cytochrome p450c-17α activity in both the ovaries and adrenals [102]. This enzyme converts progesterone to 17α-progesterone through to androstenedione, which is then converted to testosterone, causing clinical manifestations of hyperandrogenism. The elevated insulin also inhibits sex hormone binding globulin production (SHBG) from the liver, further elevating free androgen levels. Liver production of insulin-like growth factor (IGF) binding protein 1 (IGFBP-1) is lowered by insulin, resulting in increased circulating free IGF-1 which binds its receptor on the ovarian thecal cell to synergize with luteinizing hormone (LH) to increase androgen production [103]. Insulin itself is able to cause cross-talk at the IGF-1 receptor further contributing to androgen production [102]. In a systematic review of 20 trials, metformin increased circulating SHBG and lowered total testosterone, dihydroepiandrosterone sulfate (DHEA), and androstenedione levels compared to pretreatment levels [104]. P450c17-α activity was decreased by metformin in both the ovaries and the adrenal glands, resulting in reduced production of 17-α-hydroxyprogesterone [105]. In spite of the positive changes in serum androgen levels, the effect of metformin on hirsutism often is not clinically significant for the patient, and adjunct antiandrogen therapy is required [100].

Neuroendocrine defects found in PCOS patients include an increase in gonadotropin-releasing hormone (GnRH) pulse frequency, with increased LH pulse amplitude and decreased follicle-stimulating hormone (FSH) secretion [106], but whether this is an independent defect, or is tied to insulin resistance has not been fully elucidated. Although insulin can augment GnRH-induced LH secretion from pituitary cells

in vitro, insulin infusions do not influence gonadotropin levels including the response to GnRH [102].

Clinically, LH pulse amplitude in PCOS is reduced by metformin treatment accompanied by an improvement in the LH:FSH ratio [107], likely contributing to the improved menstrual regularity and ovulation seen in early studies with metformin treatment [108]. Some trials have reported that metformin alone is inferior to clomiphene in accomplishing conception, pregnancies, or live births in PCOS patients; nor does it seem that combination of metformin with clomiphene confers additional benefits [109]. However, a meta-analysis from the Cochrane collaboration using data from 16 placebo-controlled trials reported that metformin increased ovulation and clinical pregnancy rates, even when added to clomiphene, although live births were not increased [110]. Also, metformin may attenuate the ovarian response to gonadotropins for *in vitro* fertilization [111]. With these data in mind, the most recent consensus recommends metformin for PCOS patients only in the context of treatment of IGT or overt T2DM [100].

Women with PCOS have increased prevalence of IGT, metabolic syndrome, and T2DM compared to BMI-matched controls [112]. There are broad ranges for IGT and diabetes incidence when amalgamated from different studies — 1.5 to 19% for IGT and 2.6 to 8.3% for T2DM — but this is undoubtedly much higher than for the general female population [112]. Conversion from IGT to diabetes also occurs in a shorter time frame [112], so there is a possible role for metformin to delay diabetes onset. The effects of metformin on weight loss and insulin sensitivity in PCOS have been inconsistent, with some studies showing a benefit and others not.

Nonalcoholic fatty liver disease (NAFLD)

Obesity and T2DM are significant risk factors for nonalcoholic fatty liver disease (NAFLD), which is now the most common liver disorder in the developed world [113]. NAFLD is present in one quarter to half of diabetes patients [113], and is characterized by increased triglyceride accumulation in hepatocytes (steatosis), with progression to chronic inflammation and necrosis (nonalcoholic steatohepatitis or NASH), and finally fibrosis and cirrhosis in about 20% of patients with NASH [114]. Hepatocellular carcinoma (HCC) is the third cause of cancer death and can form in the setting of NASH. Patients with T2DM have a two- to threefold increased risk of developing HCC [115], and this risk soars when combined with another factor, such as chronic viral hepatitis or alcoholism. Compared to insulin or sulfonylureas, metformin may prevent the development of HCC by up to 70% in diabetes patients [116]. What is not clear is whether the apparent risk reduction is due to an "anti-tumor" property of metformin, improvements in the metabolic derangements which lead to NAFLD, or both.

Metformin alters fatty acid metabolism in the hepatocyte mediated by AMPK, inhibiting *de novo* synthesis while increasing β-oxidation [11,58]. In experimental systems, this leads to decreased accumulation of triglycerides in the liver [55].

In several clinical studies, metformin administration to overweight or obese nondiabetic or diabetic patients for periods ranging from 4 to 12 months lowered liver transaminases [113]. One study reported a rise in enzyme levels back to pretreatment levels at 3 months of treatment [113]. Even so, in a subset of their patients, liver histology showed decreased inflammation, steatosis, and/or fibrosis at 12 months [156]. Seven studies (one randomized and six open-label design) have examined liver histology in adult patients, with four reporting decreased inflammation and fibrosis [113]. All told, in a meta-analysis, metformin was not found to improve histology, lobular inflammation, hepatocyte ballooning, or fibrosis [117]. Weight loss of ≥7% improves the histologic NAFLD activity score [117], so it is unclear if the heterogeneity seen among the trials is secondary to differences in weight changes in subjects.

HIV lipodystrophy

HIV-associated lipodystrophy is characterized by dyslipidemia and insulin resistance with increased central fat and decreased peripheral and facial fat [118]. It is often, but not always, associated with highly active antiretroviral therapy (HAART), and up to 80% of patients on these medications will develop features of lipodystrophy [118]. Open label metformin (850 mg three times per day) for 2 months decreased weight, visceral fat, fasting insulin, and insulin levels during oral glucose tolerance testing in HIV patients on HAART [119]. A subsequent randomized controlled pilot study reported that 3 months of metformin therapy (500 mg twice per day) reduced weight, abdominal fat, and resulted in a 20% reduction in AUC insulin levels during an oral glucose tolerance test [120]. Extension of the study for 6 more months sustained the lowered insulin levels and caused further improvements in BMI and the cardiovascular risk marker tPA [121]. Importantly, lactate levels did not rise, given that patients on nucleoside reverse transcriptase inhibitors can have a higher risk for lactic acidosis [118]. A meta-analysis of six randomized controlled trials with 206 patients using metformin versus placebo also found decreased fasting insulin but without changes in glucose, triglycerides, LDL- or HDL-cholesterol [98]. BMI decreased but there was no effect on the waist-to-hip ratio [98]. The mean duration of treatment over all the studies was 27 months, but it is unclear if the positive effects are durable beyond that time, as HIV and lipodystrophy are chronic diseases. Also, there is no data available on effects on cardiovascular mortality with metformin in this population.

Cancer biology

From population studies, patients with diabetes have a higher cancer incidence than nondiabetics, including liver, pancreas, endometrium, colon, breast, and bladder cancer [122]. It is unclear if this is due to the existence of common risk factors for both diseases or whether hyperglycemia and/or hyperinsulinemia contribute to the increased risk by promoting cancer growth. Observational studies have hinted at a decrease in cancer incidence and mortality for diabetes patients treated with metformin including colorectal cancer, HCC, breast, and pancreatic cancer, and meta-analyses including these types of studies have reported somewhere in the range or 30–40% cancer incidence and mortality [123,124]. However, a systemic review including 14 randomized controlled trials, equivalent to 50,000 person-years, failed to find a significant effect of metformin on cancer incidence and all-cause mortality versus either usual care or other diabetes medications [125] . Nonetheless, this area clearly needs more clinical exploration, and awaits data from trials with metformin as an adjuvant to chemotherapy or prior to cancer surgery. Some of the positive effects of metformin *in vivo* could be through the lowering of glucose and insulin levels, and even circulating free IGF-1 levels which are elevated due to hyperinsulinemia [122]. Insulin can act as a mitogen, mediated through its activation of mitogen activated protein kinase (MAPK) and phosphoinositol 3-kinase/Akt pathways, which both regulate cell proliferation [126]. Akt activates mTOR (mammalian target of rapamycin) which also promotes glucose uptake into the cell [126], providing needed fuel to glycolytic pathways. The IGF-1 receptor is activated by IGF-1, or even insulin, and promotes cell proliferation as well [127].

Preclinical experiments have provided evidence that metformin can halt replication of cancer cell lines (including breast, ovarian, and prostate) *in vitro* independent of glucose and insulin [13]. One underlying mechanism may be through activation of the LKB1-AMPK pathway [13]. LKB1 was first studied in its role as a tumor suppressor before its association with AMPK was discovered. Knockdown of downstream AMPK expression attenuates the effect of metformin on cell proliferation, likely through releasing mTOR from inhibition. There are multiple additional signal transduction pathways in cancer cells that are affected by metformin *in vitro* [13], and it will to be exciting to see if these discoveries translate into improved clinical outcomes for patients with cancer.

Adverse events, contraindications, and side effects

Lactic acidosis

Humans produce $15–20\ mmol\ kg^{-1}$ of lactate per day from glycolysis and deamination of alanine to be converted to pyruvate in the liver. With biguanide inhibition of the mitochondrial respiratory chain, there is an increase in glycolysis which can result in increased lactate production. Biguanides also decrease hepatic uptake and utilization of lactate for gluconeogenesis. These actions increase the potential for biguanides to cause lactic acidosis (LA), defined by decreased arterial blood pH (<7.35), with elevated lactate levels ($>4–5\ mEq\ L^{-1}$ or $mmol\ L^{-1}$) and an anion gap. LA is the most severe adverse effect of biguanide therapy, and can be fatal in up to 50% of cases [128].

From early epidemiologic data, there were an estimated to 40–64 cases of LA per 100,000 patient-years with

phenformin [129], whereas most reports put the risk for metformin somewhere between 2 and 9 [130]. The difference is due to the lipophilic side chain of phenformin (Figure 43.1) which allows the drug to penetrate lipid and mitochondrial membranes and more potently inhibit NADH-dependent respiration compared with metformin [9]. Also, phenformin is partially metabolized in the liver through hydroxylation and nearly 1 in 10 people have a genetic polymorphism that slows hydroxylation, reducing drug clearance, and predisposing individuals to developing LA [131]. In contrast, metformin is excreted unchanged in the urine [7].

A systematic review from the Cochrane Collaboration included prospective controlled clinical trials and observational cohort studies in T2DM patients treated with metformin, alone or in combination with other medications. There were no cases of LA in 347 trials with 70,490 patient-years of treatment, even though over 40% of the prospective trials in the analysis did not exclude patients with impaired renal function [130]. The design of most clinical studies would include risk factors for LA as contraindications to metformin therapy in the exclusion criteria. Therefore, in the confines of appropriate prescribing practices, the risk of LA with metformin approaches zero [132]. Outside of clinical trials, the reality is that up to 50–70% of patients are prescribed metformin in spite of at least one contraindication, such as renal insufficiency, congestive heart failure, or liver dysfunction [133]. Nonetheless the incidence of LA remains low. In a general healthcare database from the UK with over 50,000 patients, the incidence for LA was 3.3 per 100,000 patient-years for those on metformin and was even higher for sulfonylureas at 4.8 cases [134]. It is also important to note that patients with T2DM already have a greater risk of LA than nondiabetics, as high as 9.7 episodes per 100,000 patient-years in one study, without a further increase in the risk while on metformin [135].

Only rarely has LA occurred among patients receiving metformin without any other contributory causes or conditions and, in the vast majority of cases of LA with metformin therapy, patients had concurrent illnesses which could also cause LA and precipitate the reaction. In deliberate overdose, metformin-associated LA was noted in 16% of cases, so this drug certainly is capable of causing lactic acid on its own when present in supratherapeutic levels [136]. Thus, the goal is to avoid metformin accumulation.

Globally, the prescribing threshold for acceptable renal function for metformin therapy varies widely. The U.S. Food and Drug Administration still recommends against metformin use if the creatinine is $>1.5\,\mathrm{mg\,dL^{-1}}$ in men and $>1.4\,\mathrm{mg\,dL^{-1}}$ in women. Other countries have more permissive thresholds using estimated GFR (eGFR), with metformin to be used with caution at $<60\,\mathrm{mL\,min^{-1}}$ per $1.73\,\mathrm{m^2}$ (Canada) or $<45\,\mathrm{mL\,min^{-1}}$ per $1.73\,\mathrm{m^2}$ (UK, Australia). All seem to agree that metformin is contraindicated with eGFR $<30\,\mathrm{mL\,min^{-1}}$ per $1.73\,\mathrm{m^2}$, when the clearance of metformin drops precipitously [133].

Additional named contraindications to metformin therapy are congestive heart failure requiring pharmacologic treatment (potential for hypoxia), hepatic impairment (lactate accumulation), and acute or chronic metabolic acidosis. Alcohol may potentiate the effect of metformin on lactate metabolism. Metformin therapy should not be used in patients with evidence of hypoxemia, dehydration, or sepsis. Generally, guidelines and consensus statements do not recommend use of metformin in the inpatient setting.

Metformin itself is not nephrotoxic. However, iodinated contrast agents may temporarily decrease renal function, resulting in metformin accumulation and increasing the risk of LA [137]. There is wide variation in the recommendations from radiologic professional organizations in several countries regarding metformin and contrast administration [137]. There are no documented cases of LA in metformin users with normal baseline renal function having a single computed tomography scan and a usual dose of contrast [137]. Nonetheless, the general consensus is that, in patients with normal baseline renal function, metformin should be stopped at the time of contrast administration and for 48 hours thereafter, although some organizations specify that this is required only if greater than 100 mL of contrast is administered.

Other adverse effects

The most common side effects occurring with metformin therapy are gastrointestinal in nature, occurring in 20–30% of patients [65], including diarrhea, nausea, bloating and flatulence, cramping and abdominal pain (Table 43.3). A significant percentage (20–30%) of a metformin dose is found in the feces from lack of absorption [6]. Side effects are dose-dependent but usually are transient and subside with continued treatment [138] so they rarely result in drug discontinuation. In clinical trials, only 4–6% of patients discontinued metformin due to intolerable adverse events [59]. Gastrointestinal tolerability can be improved by initiating metformin therapy at low doses with slow titration upward, taking metformin doses with meals, and using metformin XR which has a lower frequency of gastrointestinal adverse events than metformin IR [6,69].

Up to 30% of patients will have decreased absorption of vitamin B12, with decreased levels detected as early as 4 months of therapy, and symptomatic deficiency developing after 5–10 years [60]. In some studies, decreased B12 levels are accompanied by decreased folate and elevated homocysteine [139]. Rarely, the B12 deficiency can be severe and manifest as megaloblastic anemia or peripheral neuropathy [140,141]. Because B12 deficiency is progressive over duration of metformin therapy, screening and appropriate supplementation is supported by some in the field [142], although the appropriate intervals for testing are not guided by consensus statements at this time.

Conclusion

Metformin is first line and central to T2DM treatment. Its primary target is liver glucose production, but it also has

Table 43.3 Frequency (%) of adverse events occurring in more than 5% of patients receiving metformin immediate-release and extended-release therapy and occurring more frequently than with placebo in controlled clinical trials[a]

Adverse event	Metformin ($n = 141$)	Placebo ($n = 145$)	Metformin extended-release ($n = 781$)	Placebo ($n = 195$)
Diarrhea	53.5	11.7	9.6	2.6
Nausea/vomiting	25.5	8.3	6.5	1.5
Flatulence	12.1	5.5	—	—
Asthenia	9.2	5.5	—	—
Indigestion	7.1	4.1	—	—
Abdominal discomfort	6.4	4.8	—	—
Headache	5.7	4.8	—	—

important effects on glucose uptake and fatty acid metabolism in peripheral tissues. Some of these consequences are mediated by activation of AMPK, while others findings may be independent of AMPK due to direct effects on mitochondrial respiration. Metformin is especially amenable to use as a combination therapy with other oral diabetes agents, allowing for targeting of multiple defects present in T2DM. There also is potential for metformin use in other diseases with metabolic derangements including diabetes in pregnancy, polycystic ovary syndrome, nonalcoholic fatty liver disease, HIV lipodystrophy, and even cancer. However, in most of these disorders, further clinical data is needed before metformin will be approved and accepted as a mainstream therapy.

PPAR agonists in the treatment of diabetes

Sunder Mudaliar and Robert R. Henry

Section of Diabetes/Metabolism, VA San Diego HealthCare System, San Diego, CA, USA

Key points

- Insulin resistance is a major pathophysiologic abnormality in type 2 diabetes and is intricately involved in the development of not only hyperglycemia, but also dyslipidemia, hypertension, and atherosclerosis.

- The PPARs are a family of nuclear receptors comprised of three subtypes designated PPARα, PPARγ, and PPARδ.

- The thiazolidinediones are potent insulin sensitizers and through their PPARγ agonist effects, they improve insulin sensitivity and glycemic control, and also have potentially beneficial effects on lipid metabolism, vascular tone, and endothelial function.

- Pioglitazone is the only PPARγ still generally available and has favorable effects on diabetes prevention, lipid parameters, and surrogate CV markers. In one study, it reduced the composite secondary outcome of all-cause mortality, nonfatal myocardial infarction, and stroke in patients with type 2 diabetes and high CVD risk.

- Dual PPARα/γ agonists are currently being studied and seek to combine the glucose-lowering/insulin-sensitizing PPARγ agonist properties of the thiazolidinediones with the lipid-modifying PPARγ properties of fibrates. The development of such dual agonists would help improve the management of both type 2 diabetes and diabetic dyslipidemia.

Introduction

Type 2 diabetes (T2DM) is a chronic disease characterized by hyperglycemia and numerous other metabolic abnormalities which lead to disabling micro- and macrovascular complications. It is one of the leading causes of premature cardiovascular morbidity and mortality and is estimated to affect more than 366 million people worldwide in 2011 and 552 million people by 2030 [1]. Three major pathophysiologic abnormalities contribute to the development of hyperglycemia in patients with T2DM: impaired insulin secretion, excessive hepatic glucose output, and insulin resistance in skeletal muscle, liver, and adipose tissue [2]. Insulin resistance is intricately involved

in the development of not only hyperglycemia, but also dyslipidemia, hypertension, hypercoagulation, vasculopathy, and ultimately, premature atherosclerotic cardiovascular disease [3]. This cluster of metabolic abnormalities has been variously termed the "insulin-resistance syndrome" or the "metabolic syndrome" [3]. The thiazolidinediones (TZDs) are potent insulin sensitizers and through their PPARγ effects improve insulin sensitivity at target tissues—adipose tissue, skeletal muscle, and liver and improve glycemic control when used as monotherapy and in combination with other antihyperglycemic agents [4]. Additionally, the TZDs have beneficial effects on blood pressure, vascular tone, and endothelial function. However, these effects have not always translated into improved cardiovascular outcomes. Further, the use of these agents has been impacted by adverse effects reported including weight gain, bone loss, fluid retention, edema and precipitation of CHF as well as a possible association with bladder cancer.

Although three compounds in this class were approved for clinical use, only one agent pioglitazone (Actos®) is currently in common clinical use in the United States. The first agent in this class, troglitazone (Rezulin®) was marketed in the US from March 1997 until it was withdrawn in March 2000, due to risks of hepatotoxicity. Rosiglitazone (Avandia®) was approved in the US in May 1999, but in 2010, after the publication of epidemiologic evidence of possible greater incidence of cardiovascular events [5] the use of rosiglitazone was severely restricted in the US and it is currently not available in several countries. Recently, in June 2013, after an independent readjudication of the Rosiglitazone Evaluated for Cardiovascular Outcomes and Regulation of Glycemia in Diabetes (RECORD) trial, the FDA concluded that rosiglitazone does not increase the risk for adverse cardiovascular outcomes. However, the restrictions on its use have not been lifted. As regards pioglitazone, due to the association with bladder cancer, the drug has been withdrawn from clinical use in France and Germany. In the US, the Food and Drug Administration (FDA), after an ongoing safety review of pioglitazone, updated the drug

labels for pioglitazone-containing medicines to include safety information that the use of pioglitazone for more than 1 year may be associated with an increased risk of bladder cancer. The FDA also recommends that pioglitazone not be used in patients with active bladder cancer and be used with caution in patients with a prior history of bladder cancer. The FDA continues to evaluate data from an ongoing 10-year epidemiologic study; (http://www.fda.gov/Safety/MedWatch/SafetyInformation/ SafetyAlertsforHumanMedicalProducts/ucm226257.htm). Interim data from the 8-year follow-up of this study of 193,099 eligible men and women with diabetes mellitus suggest that in the cohort analysis, there is no overall statistically significant increased risk of bladder cancer among patients ever treated with pioglitazone; (http://general.takedapharm.com/Trial-Disclosure/01-03-TL-OPI-524-8-year-Interim-Report.pdf). Despite all the above, the TZDs still have a role in the treatment of T2DM, since this is the only class of drugs that primarily targets insulin resistance. These drugs can be used in patients with renal impairment and there is a low incidence of hypoglycemia with these agents. Further, pioglitazone, the only agent in this class still readily available, also has favorable effects on diabetes prevention, lipid parameters, and in one study, it reduced the composite secondary outcome of all-cause mortality, nonfatal myocardial infarction, and stroke in patients with T2DM who have a high risk of macrovascular events.

In this chapter, we review the mechanism of action, pharmacology, and clinical use of the thiazolidinedione PPARγ agonist, pioglitazone and also provide a brief description of dual PPAR agonists still in clinical development.

Mechanism of action

The PPARs (peroxisome proliferator-activated receptors) are a family of nuclear receptors comprised of three subtypes designated PPARα, PPARγ, and PPARδ or β (Figure 44.1) [6]. Activation of PPARs leads to the formation of heterodimers with retinoid-X receptors (RXRs). These PPAR-RXR dimers bind to DNA-specific sequences called peroxisome proliferator response elements, which stimulate or dampen the transcription of target genes. PPAR isoforms vary in selectivity and sensitivity to ligands and recruit distinct co-activators/co-repressors, resulting in the regulation of different sets of genes [6]. PPARα regulates genes involved in fatty acid uptake and oxidation, inflammation, and vascular function. PPARδ regulates genes involved in fatty acid metabolism, inflammation, and macrophage lipid homeostasis. PPARγ receptors are found in key target tissues and are important regulators of adipocyte differentiation, hepatic and skeletal muscle glucose metabolism, lipid homeostasis, macrophage function, and vascular endothelial biology [4,6] (Figure 44.2).

The TZDs are highly selective and potent agonists for PPARγ and favorably influence the expression of several genes involved in glucose metabolism, including adiponectin,

Peroxisome Proliferator-Activated Receptors (PPARs)

	PPAR σ	PPAR δ	PPAR γ
Tissue expression profile	Liver, kidney, adrenal, skeletal muscle, adipose tissue, vascular tissues	Ubiquitous	Adipose tissues, skeletal muscle, heart, liver, kidney, gut, macrophages, vascular tissues, islet cells γ1 dominant isoform in muscle γ2 key regulator in fat tissue
Metabolic effects	Vascular, anti-inflammatory, fat oxidation	Reverse cholesterol transport	Adipogenesis, fat redistribution, glucose metabolism, fat oxidation, vascular, anti-inflammatory

Figure 44.1 Tissue expression profile and metabolic effects of the peroxisome proliferator-activated receptors (PPARs).

GLUT1, GLUT4, leptin, TNFα, Akt (protein kinase B), and hepatic glucokinase [4,6,7].

It is important to note that major aspects of PPARγ action are still unresolved. It is not known why synthetic activation of PPARγ produces dramatic antidiabetic effects when there is no general deficiency in PPARγ function in obesity/insulin-resistant states. Also, while antidiabetic effects of PPARγ agonist drugs correlate well with binding affinities, some compounds with poor agonist activities have potent antidiabetic effects. In a recent study, Choi et al. demonstrated that phosphorylation of PPARγ by the protein kinase Cdk5 does not activate/suppress general receptor transcriptional activity, but changes the expression of specific genes like adiponectin. Cdk5-mediated phosphorylation of PPARγ is linked to obesity induced in mice by high-fat feeding. Several antidiabetic PPARγ ligands, with or without classical agonist properties, directly inhibit the action of Cdk5 on PPARγ and restore a more normal, nondiabetic pattern of gene expression. In addition, inhibition of this PPARγ phosphorylation in humans by TZDs is closely associated with its antidiabetic effects (Figure 44.3). This study suggests a novel model for a Cdk5-PPARγ link in the pathogenesis of obesity/diabetes and for the therapeutic action of PPARγ ligands in these disorders [8]. In a follow-up study, Choi et al. described a novel synthetic compound—SR1664 with a unique mode of binding to PPARγ, lacking classical transcriptional agonism and able to block Cdk5-mediated phosphorylation in cultured adipocytes/insulin-resistant mice [9]. Moreover, SR1664 had potent antidiabetic activity without causing fluid retention and weight gain like the TZDs. Also, unlike TZDs, SR1664 did not interfere with bone formation in culture. These data illustrate that newer antidiabetes drugs can be developed by specifically targeting the Cdk5-mediated phosphorylation of PPARγ.

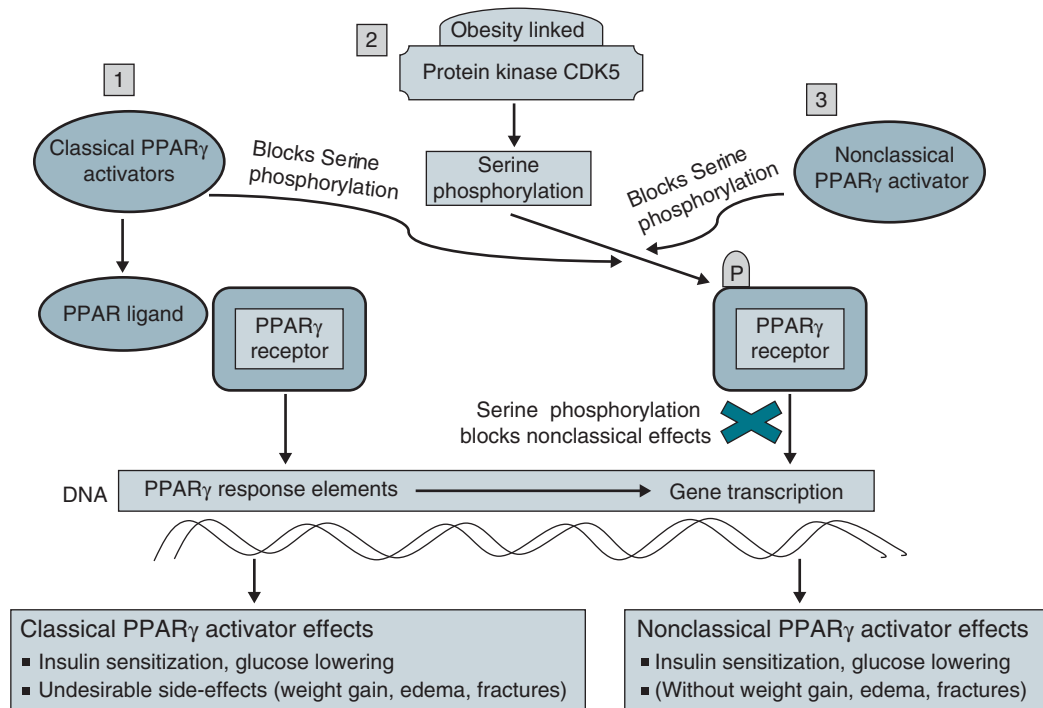
In addition to improving insulin sensitivity and glucose metabolism, PPARγ agonism may also mediate the antihypertensive and anti-atherosclerotic effects of the TZDs. Human smooth muscle cells (VSMCs) express mRNA and nuclear receptors for PPARγ 1 [10]. These receptors are upregulated during vascular injury and are present in early human atheroma
Figure 44.2 Possible sites of sensitizing actions of the thiazolidinediones.


Figure 44.3 Classical and nonclassical pathways of PPARγ activation.

1 Activation of the PPARγ receptor by ligands like pioglitazone results in the classical PPARγ activation effects like improved insulin sensitivity and glucose lowering along with the undesirable side-effects of weight gain, edema, and bone effects.

2 Cdk5-mediated serine phosphorylation of PPARγ is linked to obesity induced in mice by high-fat feeding. Phosphorylation of PPARγ by the protein kinase Cdk5 does not activate/suppress general receptor transcriptional activity, but changes the expression of specific genes like adiponectin, leading to decreased insulin sensitivity.

3 Several antidiabetic PPARγ ligands, with or without classical PPARγ agonist properties, directly inhibit the phosphorylation of Cdk5 on PPARγ and restore a more normal, nondiabetic pattern of gene expression.

and precursor lesions. Pharmacologic activation of PPARγ with pioglitazone inhibits VSMCs proliferation and migration with the potential to limit restenosis and atherosclerosis [11].

Also of note, dual PPARα/γ agonists are currently in development and seek to combine the glucose-lowering/insulin-sensitizing PPARγ agonist properties of the TZDs and the lipid-modifying PPARγ properties of fibrates. The use of such dual agonists should improve the management of T2DM and diabetic dyslipidemia. Aleglitazar is a potent dual PPAR agonist with balanced affinity for the PPARα and PPARγ isoforms. The pattern of gene activation with aleglitazar is distinct from that achieved by the combination of fenofibrate and pioglitazone [12]. However, in July 2013, following the results of a regular safety review of the aleglitazar AleCardio phase III trial, the independent Data and Safety Monitoring Board (DSMB) recommended a halt to the trial due to safety signals and lack of efficacy. Based on this recommendation, the further development of aleglitazar has been stopped.

Glycemic effects

As potent insulin sensitizers, the TZDs have major effects on glucose metabolism that result in significantly lower blood glucose levels in insulin-resistant patients with T2DM (Table 44.1). Several studies in populations across the world, have documented the glucose-lowering effects of pioglitazone when used as monotherapy agent and in combination with sulfonylureas, metformin, dipeptidyl peptidase-4 (DPP-4) inhibitors, glucagon-like peptide-1 (GLP-1) receptor activators and insulin. In this context it must be pointed out that although pioglitazone is approved by the FDA in the United States for use as monotherapy and in combination with the sulfonylureas, metformin, and with insulin, in Europe, pioglitazone is not approved for use in combination with insulin.

Pioglitazone monotherapy

In a large multicenter, double-blind, placebo-controlled clinical trial, 408 patients with HbA1c >7.0% and FPG >140 mg dL^{-1} were randomized to pioglitazone monotherapy or placebo [13]. After 26 weeks, patients treated with 15, 30, or 45 mg pioglitazone had significant mean decreases in HbA1c (range −1.00 to −1.60% difference from placebo) and FPG (−39 to −65 mg dL^{-1} difference from placebo). The decreases in FPG were observed as early as the second week of therapy; maximal decreases occurred after 10–14 weeks and were maintained until the end of therapy. In addition, in all pioglitazone groups, there were significant mean decreases in triglycerides, increases in HDL-cholesterol (HDL-C), and only small changes in total cholesterol and LDL. Of interest, the subset of patients naïve to

Table 44.1 Relative efficacy of pioglitazone

	Reduction in fasting plasma glucose (mg dL^{-1}) Mean change from control group	Reduction in HbA1c (%)
Monotherapy		
Pioglitazone 15 mg	39	1.0
Pioglitazone 30 mg	41–58	1.0–1.5
Pioglitazone 45 mg	65–68	1.5–1.6
Combination with sulfonylureas		
Pioglitazone 15 mg	39	0.9
Pioglitazone 30 mg	58	1.3
Combination with Metformin		
Pioglitazone 30 mg	38	0.8
Combination with DPP-4 agents		
Pioglitazone 30/45 mg	15–20	0.4–0.7
Combination with GLP-1 agonists (Exenatide 10 mcg BID)		
Pioglitazone 30/45 mg (or Rosiglitazone 4/8 mg) ± Metformin	30	0.98
Combination with insulin		
Pioglitazone 15 mg	35	1.0
Pioglitazone 30 mg	40	1.3

Since the above data were not obtained from simultaneous trials, the comparative data is only a rough approximation of the relative effectiveness as stage, severity of hyperglycemia, and type of patients studied varied in the above studies.
Source: References [13,14,17–23].

oral antidiabetic therapy had greater improvements in HbA1c and FPG (difference from placebo of -2.55% and $-80\,mg\,dL^{-1}$ for the 45 mg group) compared with previously treated patients. The overall adverse event profile of pioglitazone was similar to that of placebo. Similar results were reported in another 23-week, placebo-controlled monotherapy trial which demonstrated that compared with placebo, 30 mg daily of pioglitazone significantly reduced FPG by $58\,mg\,dL^{-1}$ and HbA1c by 1.37% [14]. In addition, there were significant improvements in measures of insulin sensitivity and β-cell function. In the studies above, pioglitazone monotherapy was associated with weight gain of 1.3 to 1.5 kg from baseline with the 15/30 mg dose and 2.8 kg with the 45 mg dose, compared to a decrease of about 1.5 kg with placebo.

In the context of monotherapy, it is noteworthy that there are few prospective clinical trials in patients with T2DM that have directly compared the impact of the various available antidiabetic agents on metabolic and clinical outcomes. The largest of these, the UKPDS [15] observed a progressive failure of the glucose-lowering therapies used (metformin, sulfonylureas, and insulin) to maintain glycemic control. In this study, the stepwise addition of antihyperglycemic agents to achieve glycemic goals resulted in substantial therapeutic overlap between the groups, making it difficult to analyze the effects of individual therapies. Importantly, the only insulin sensitizer available at the time of the UKPDS was metformin. Since the TZDs are more potent insulin sensitizers and also have beneficial effects on β-cell function, it would be expected that their use as monotherapy would provide more durable glucose control. This was demonstrated in the ADOPT study (A Diabetes Outcome Progression Trial) [16] with rosiglitazone. In this study, 4360 recently diagnosed, treatment-naïve patients with T2DM were randomized to rosiglitazone, metformin, or glyburide in a double-blind manner and treated for a median of 4 years. The cumulative incidence of monotherapy failure, defined as a confirmed level of fasting plasma glucose of more than $180\,mg\,dL^{-1}$, by Kaplan-Meier analysis at 5 years was 15% with rosiglitazone, 21% with metformin, and 34% with glyburide. This represented a significant risk reduction of 32% for rosiglitazone, as compared with metformin, and 63%, as compared with glyburide. So far no similar data is available with pioglitazone.

Combination therapy with sulfonylureas

The addition of pioglitazone to existing sulfonylurea therapy has been shown to significantly improve glycemic control in several large studies. In a large multicenter study, 560 patients on a stable regimen of a sulfonylurea and with HbA1c levels >8.0% [17] were randomly assigned to receive sulfonylurea plus either once-daily pioglitazone 15 or 30 mg or placebo. After 16 weeks, as compared with patients treated with placebo, those receiving pioglitazone 15 mg and 30 mg had significant decreases from baseline in HbA1c by 0.9% and 1.3%, respectively. FPG levels also decreased by $39\,mg\,dL^{-1}$ and $58\,mg\,dL^{-1}$ with pioglitazone

15 mg and 30 mg pioglitazone. Both pioglitazone groups had significant improvements in lipid levels and the drug was well tolerated with similar rates of adverse events in all groups. Of note, body weight increased by a mean of 1.9 kg and 2.9 kg in the 15 mg and 30 mg pioglitazone groups and this increase correlated with improvements in glycemic control. There was a decrease of 0.8 kg in the placebo group.

Combination with metformin

In obese type 2 diabetic patients inadequately controlled on metformin alone, the addition of a thiazolidinedione further improves glycemic control, insulin sensitivity, and β-cell function to a clinically important extent. In a multicenter study, 328 patients with T2DM who had suboptimal control on maximum doses of metformin [18] were randomized to either pioglitazone+metformin or placebo+metformin. After 16 weeks, the addition of pioglitazone 30 mg significantly decreased FPG levels by $38\,mg\,dL^{-1}$ and HbA1c by -0.83% compared with the placebo. Body weight increased by a mean of 0.95 kg with pioglitazone and decreased by 1.36 kg with placebo. One hundred and fifty-four of the study subjects entered an open-label phase where all patients were treated with pioglitazone 30 mg+metformin for 72 weeks and had mean decreases from baseline of 1.36% in HbA1c and $63\,mg\,dL^{-1}$ in FPG.

Combination with DPP-4 inhibitor

The combination of pioglitazone and DPP-4 inhibitors has been studied in those failing on pioglitazone±metformin/SU treatment. In these patients, large, multicenter, placebo-controlled studies have demonstrated reductions in HbA1c and FPG of -0.4–0.7% and 15–$20\,mg\,dL^{-1}$, respectively, with no significant change in body weight compared to placebo [19].

Combination with GLP-1 agonist

A thiazolidinedione and GLP-1 agonist combination has also been demonstrated to provide effective glucose control. In a multicenter study, 233 patients with T2DM who were suboptimally controlled with thiazolidinedione treatment (pioglitazone/rosiglitazone with or without metformin) were randomized to exenatide or placebo [20]. At 16 weeks, compared to placebo, the addition of exenatide reduced HbA1c by -0.98% (from a baseline of 7.9%), and body weight by 1.51 kg (baseline 97 kg). As expected, there were more GI side-effects in the exenatide arm and hypoglycemia occurred in 11% versus 7% in the placebo group. Of note, although patients in this study experienced modest weight loss, the study was not designed to determine whether simultaneous initiation of exenatide and TZD therapies would prevent weight gain associated with the use of TZDs. Also, weight reduction occurred without the use of additional lifestyle interventions as part of the study protocol.

Combination with insulin

At the outset, it must be stated that the use of TZDs in patients with T2DM who are on insulin treatment is not approved in

Europe. In the US, pioglitazone is approved for use in combination with insulin. However, the FDA has cautioned that because combination thiazolidinedione and insulin therapy is associated with an increased incidence of pedal edema and a potentially greater propensity for patients to develop CHF, pioglitazone should be used prudently in patients with pre-existing pedal edema, especially in those who have evidence of milder degrees of heart failure (NYHA Class 1 and 2). In patients with NYHA Class 3 and 4 cardiac status, treatment with pioglitazone is not recommended.

The efficacy and safety of pioglitazone in insulin-treated patients with T2DM was evaluated in a large, multicenter study in which 566 patients with T2DM on stable insulin regimens for >30 days and HbA1c > 8.0% were randomized to receive either 15 or 30 mg pioglitazone, or placebo [21]. Per study protocol, the insulin dose remained unchanged, but could be decreased in response to hypoglycemia. At the end of double-blind treatment, relative to baseline, patients receiving pioglitazone (15 mg or 30 mg) showed statistically significant mean decreases HbA1c of −1.0 and −1.3%. Although the incidence of adverse events was similar in all treatment groups, the incidences of weight increase, hypoglycemia and edema were higher among patients receiving insulin+pioglitazone. In this study, pioglitazone also significantly improved HDL-C levels (mean increases ranging from +7.1% to +9.3%) compared with baseline or placebo. The 30 mg dose also significantly reduced mean triglyceride levels (−23.7%) compared with placebo. No consistent changes in TC or LDL-C levels were observed.

A recent meta-analysis of eight trials examined the benefits of adding pioglitazone to an insulin regimen in 3092 patients with T2DM. It was found that pioglitazone doses of up to 45 mg d^{-1} were associated with a mean reduction in HbA1c of 0.58% and an average weight gain of 3 kg along with slightly more frequent hypoglycemia (relative risk 1.27; $p = 0.06$). Pioglitazone use was also associated with significantly less insulin requirements (weighted mean difference −0.19 U kg^{-1} d^{-1} or −12.03 U d^{-1}). Peripheral edema was more frequent in the pioglitazone groups and where reported, HDL-C tended to increase with pioglitazone. None of the studies reported on fractures in women, and data on cardiovascular events were inconclusive, with most studies being too short or too small to assess these long-term outcomes [22].

Metabolic effects

As potent insulin sensitizers, the PPARγ agonists not only improve glycemic control, but also have multiple metabolic effects on peripheral insulin sensitivity, β-cell function, diabetes prevention, lipid metabolism, and body fat distribution [4].

Insulin sensitivity
Several studies have documented the *in vivo* effects of TZDs on peripheral insulin action in patients with T2DM, and in other insulin-resistant states like impaired glucose tolerance (IGT), polycystic ovary disease, previous gestational diabetes, and lipodystrophy [4]. Some of these studies have used the hyperinsulinemic-euglycemic clamp study which is currently considered the "gold standard" to evaluate peripheral insulin sensitivity, while others have used the frequently sampled intravenous glucose tolerance test (FSIVGTT) and other less direct methods, including the insulin tolerance test, the intravenous or oral glucose tolerance test and the HOMA-S to assess thiazolidinedione effects on insulin sensitivity. In all these studies, the TZDs have improved insulin-mediated peripheral glucose utilization in obese, insulin-resistant subjects with T2DM by approximately 30–100% [4].

In an elegant study using the two-step (40 and 160 mU min^{-1} per m^2) hyperinsulinemic clamp, indirect calorimetry and hepatic tracer technology, Miyazaki et al. evaluated hepatic and peripheral insulin sensitivity in 23 obese diabetic patients on a stable dose of sulfonylurea [23]. After 16 weeks, the addition of pioglitazone 45 mg was associated with significant decreases in FPG (184 to 135 mg dL^{-1}), HbA1c (8.9 to 7.2 %) and plasma FFA levels. Endogenous glucose production (EGP) during the first insulin clamp step was significantly decreased after pioglitazone treatment, whereas insulin-stimulated total and nonoxidative glucose disposal during the second insulin clamp was increased by 38% ($p < 0.01$). The change in FPG was related to the change in basal EGP, EGP during the first insulin clamp step, and total glucose disposal during the second insulin clamp step. These results suggest that pioglitazone therapy in type 2 diabetic patients decreases plasma glucose by improving hepatic and peripheral (muscle) tissue sensitivity to insulin.

In a large, international study, Pavo et al. studied the effect of 32 weeks of monotherapy with either pioglitazone or metformin on glycemic control and insulin sensitivity in 205 recently diagnosed type 2 diabetes patients who were naïve to antidiabetic therapy [24]. In this study, pioglitazone was comparable to metformin in improving glycemic control as measured by HbA1c and FPG (decreases of ~1.3% and ~54 mg dL^{-1}). However, insulin sensitivity (as assessed by HOMA-S) increased significantly by 17.4% in the pioglitazone group compared with a nonsignificant increase of 8.9% in the metformin group.

Beta-cell function
Along with defects in action in insulin sensitivity, defects in insulin secretion from the pancreatic β cells also play a major role in the pathogenesis of T2DM. Data from the UKPDS and other studies have suggested that β-cell function decreases with duration of T2DM whether treated with diet therapy or antihyperglycemic therapy [25,26]. Since PPARγ is expressed in human islet cells, both at the mRNA and protein levels, it is possible that the TZDs have direct effects on human pancreatic endocrine cells [27]. At present however, it is not possible to image β-cell mass *in vivo* in humans with sufficient accuracy and specificity. The best available methods of β-cell function *in vivo* are measurements of serum insulin levels at baseline and

after stimulation with glucose and arginine. Other methods include the homeostatic model assessment (HOMA), the intravenous glucose tolerance test, the hyperglycemic clamp and the pro-insulin to insulin ratio.

In one of the early studies of β-cell function [28], Miyazaki et al. found an increase in plasma insulin response during OGTT in diabetic patients treated with 30 and 45 mg d^{-1} of pioglitazone. An increased or maintained plasma insulin response in the presence of a decreased plasma glucose concentration suggests an improvement in β-cell function. The variable effect of TZDs on the plasma insulin response to a glucose challenge may be explained by two opposing effects. Firstly, a decrease in fasting and postprandial glucose concentrations leads to reduced "glucose toxicity" on the β cell and improved insulin secretion, and secondly, with the improvement in insulin sensitivity, there is a reduced requirement for insulin secretion.

In another study from the UK, 30 subjects with diet-controlled T2DM were randomized to treatment with pioglitazone or placebo. After 3 months, in the pioglitazone group, along with significant improvement in glycemic control, insulin sensitivity and the pro-insulin to insulin ratio, there was a significant improvement in HOMA-S: +11.5% versus −2.0% with placebo. However, there was no change in stimulated β-cell function as determined by hyperglycemic clamp test. As expected, there was a significant reduction in the HbA1c by 0.6% with pioglitazone compared with placebo. There was no significant weight gain associated with pioglitazone therapy: +0.7 kg versus +1.1 kg in the placebo group [29].

From the studies above, it is clear that the TZDs as PPARγ agonists have only modest β-cell effects in humans and reduced "glucose toxicity" alone may account for these effects. In contrast, in a mouse model, pioglitazone treatment had both an acute effect to preserve β-cell mass in diabetic mice directly by acceleration of cell differentiation/proliferation and suppression of apoptosis; and a chronic indirect effect through amelioration of the underlying metabolic disorder and deceleration of oxidative stress [30].

Diabetes prevention

It is well recognized that subjects with impaired glucose tolerance (IGT: plasma glucose between 140 and 199 mg dL^{-1} 2 hours after a 75 gm oral glucose load) and impaired fasting glucose (IFG: plasma glucose between 100 and 125 mg dL^{-1}) are not only insulin resistant, but also at high risk to progress to T2DM. Since the TZDs are potent insulin sensitizers, they have the potential to prevent T2DM in high-risk populations with prediabetes. In the landmark US Diabetes Prevention Program [31], among individuals with IGT and high FPG (95–125 mg dL^{-1}), troglitazone use was associated with a robust 75% reduction in the incidence of diabetes compared to the placebo group [32]. In the same period (mean 0.9 years), there was a 57% reduction in the intensive lifestyle group and a 44% reduction in the metformin group. Of note, after troglitazone withdrawal due to liver toxicity, the diabetes incidence

rate increased to that of the placebo group, thereby indicating that the protective effect did not persist after the drug was stopped. In the DREAM study [33], rosiglitazone at 8 mg daily for 3 years substantially reduced incident T2DM by 60% and also increased the likelihood of regression to normoglycemia in adults with IFG, IGT, or both. There was more heart failure in the rosiglitazone group. Evidence for diabetes prevention with pioglitazone is available from the ACT Now study in which 602 patients were randomized to pioglitazone or placebo [34]. After a median follow-up of 2.4 years, as compared with placebo, pioglitazone reduced the risk of conversion from IGT to T2DM by 72%. In addition, significantly more people converted to normal glucose tolerance with pioglitazone 48% versus 28% in the placebo group. Pioglitazone therapy was also associated with significant decreases in diastolic blood pressure (2.0 mmHg vs. 0.0 mmHg); reduced rate of carotid intima-media thickening (31.5%), and a greater increase in the level of HDL-C (7.35 mg dL^{-1} vs. 4.5 mg dL^{-1}). As expected, weight gain was greater with pioglitazone than with placebo (3.9 kg vs. 0.77 kg) and edema was more frequent (12.9% vs. 6.4%). Although the evidence for diabetes prevention with the TZDs is strong, one has to keep in mind the risks for undue weight gain, edema, precipitation of CHF, bone fractures, and association with bladder cancer in some subjects. However, in selected subjects in whom the benefits outweigh the risks, pioglitazone use for diabetes prevention remains a potential option.

Lipids

In T2DM, the major quantitative change in lipid levels is an elevation in triglyceride-rich lipoproteins, a decrease in HDL-C concentrations and LDL-C levels that are often quantitatively similar to that in the general population [3]. However, qualitative changes in the composition of the LDL molecule, including an increase in the proportion of small, dense LDL which is prone to glycation and oxidation, tend to make it more atherogenic [3]. This diabetic dyslipidemic profile is closely related to underlying insulin resistance and may, in part, be responsible for the increased cardiovascular morbidity and mortality in type 2 diabetic patients. By improving glucose tolerance and reducing insulin resistance, the TZDs have the potential to favorably influence diabetic dyslipidemia. Treatment with the TZDs increases both HDL-C and LDL-C with variable effects on triglycerides. There are also differences between the TZDs. This was demonstrated in a double-blind, head-to-head study in 802 subjects with T2DM (diet/monotherapy treated) and dyslipidemia (treatment naïve) who were randomized to either pioglitazone or rosiglitazone. After 24 weeks, despite equivalent glycemic control with both agents, there was greater lowering of triglyceride levels by pioglitazone (−51.9 mg dL^{-1} vs. +13.1 mg dL^{-1} with rosiglitazone; $p < 0.001$) [35]. Additionally, the increase in HDL-C was significantly greater (5.2 vs. 2.4 mg dL^{-1}) and the increase in LDL-C was significantly less (12.3 vs. 21.3 mg dL^{-1}) for pioglitazone compared with rosiglitazone. LDL particle concentration was also reduced

with pioglitazone and increased with rosiglitazone ($p < 0.001$), while LDL particle size increased more with pioglitazone ($p < 0.005$). Thus in this study, pioglitazone and rosiglitazone had significantly different effects on plasma lipids independent of glycemic control or concomitant lipid-lowering treatment.

It is possible that these differential effects on lipids may account for the different cardiovascular outcomes with these agents. While rosiglitazone has not been associated with improvements in cardiovascular morbidity, pioglitazone may have cardiovascular benefits. In the large PROactive study, 5238 patients with T2DM who had evidence of macrovascular disease were randomized to pioglitazone or placebo [36]. In this study, as expected, LDL-C significantly increased by 7.2% with pioglitazone versus 4.9% with placebo. Although this increase is potentially detrimental, LDL subparticle analyses revealed a marked shift in the LDL particle size, resulting in more of the less atherogenic, buoyant Type A LDL particle and a decrease in the pro-atherogenic, small, dense Type B LDL particle levels [36]. Although the primary endpoint did not meet statistical significance, the main composite secondary endpoint of all-cause mortality, nonfatal myocardial infarction, and stroke was significantly lower by 16% in the pioglitazone group.

Adipose tissue

One of the intriguing aspects of treatment with the TZDs has been the observation that although patients treated with the TZDs significantly improve their insulin sensitivity and glucose and lipid profiles, they tend to gain weight and accumulate adipose tissue. Considerable research has focused on the sites and nature of this adipose tissue weight gain. It is well known that the TZDs, through PPARγ activation cause preadipocytes to differentiate into mature fat cells and also cause the induction of key enzymes involved in lipogenesis [37]. At the tissue level, *in vitro* studies have demonstrated that the TZDs specifically promote the differentiation of pre-adipocytes into adipocytes in subcutaneous fat and not in omental fat [38]. Site differences in adipose tissue function appear to have implications for insulin-resistant conditions. In mature adipose tissue, subcutaneous adipocytes have higher leptin secretion, similar tumor necrosis factor-α secretion, and lower catecholamine-stimulated lipolysis as compared with omental adipocytes [39]. Thus it would appear that the accumulation of subcutaneous fat rather that visceral (omental) fat may be beneficial in terms of promoting insulin sensitivity.

In vivo studies in humans confirm that TZD treatment produces a shift in adipose tissue distribution from omental to the subcutaneous compartment. Determinations of fat distribution after pioglitazone therapy demonstrate a greater accumulation in the subcutaneous adipose tissue compartment at the expense of visceral fat. Miyazaki and coworkers [40] examined the effect of pioglitazone on abdominal fat distribution in 13 type 2 diabetic patients who were being treated with a stable dose of sulfonylurea ($n = 7$) or with diet alone ($n = 6$) and received pioglitazone 45 mg d^{-1} for 16 weeks. Before and after

pioglitazone treatment, subjects underwent a 75 g oral glucose tolerance test (OGTT) and an insulin clamp. Abdominal fat distribution was evaluated using magnetic resonance imaging at L4-5. After 16 weeks of pioglitazone treatment, there were significant improvements in FPG (179 to 140 mg dL^{-1}, HbA1c 8.6 to 7.2% along with decreases in endogenous glucose production and fasting plasma FFA levels. The improvement in hepatic and peripheral tissue insulin sensitivity occurred despite significant increases in body weight (82 to 85 kg); total fat mass (27 to 30 kg); and subcutaneous fat area at L4/5 (301 to 342 cm^2). On the other hand, visceral fat area at L4-5 decreased from 144 to 131 cm^2 ($p < 0.05$); and the ratio of visceral to SQ fat decreased from 0.59 to 0.44; $p < 0.01$). In the postabsorptive state hepatic insulin resistance correlated positively with visceral fat area ($r = 0.55$; $p < 0.01$) and the glucose metabolic clearance rates (MCRs) during the insulin clamp steps were negatively correlated with the visceral fat area [40]. These results demonstrate that a shift in fat distribution from visceral to subcutaneous adipose depots after pioglitazone treatment is associated with improvements in hepatic and peripheral tissue sensitivity to insulin. In another recent study in obese patients with T2DM with poor glycemic control [41], it was noted that intensification of insulin therapy alone for 3–4 months caused modest weight gain (1.7 kg) and no change in body fat distribution, lean body mass (LBM), or liver fat. In contrast, the addition of pioglitazone, at equivalent glycemia, caused greater weight gain (4.9 kg) and increases in body fat mass mainly in the subcutaneous adipose tissue compartment with a trend towards a decrease in visceral adipose tissue and liver fat and an increase in LBM. The authors concluded that these changes in fat distribution may contribute to the beneficial effects of pioglitazone, despite greater weight gain.

Cardiovascular effects

Ultimately, up to 80% of type 2 diabetics die from macrovascular cardiovascular disease. An added advantage for any diabetes drug is a beneficial effect to improve cardiovascular risk factors. Pioglitazone has multiple beneficial effects on the cardiovascular system and these are detailed below and in Table 44.2.

Myocardial function and blood flow

Myocardial blood flow is an important determinant of LV function. In a recent double-blind, placebo-controlled study, 26 patients with familial combined hyperlipidemia treated with conventional lipid-lowering therapy, were randomized to pioglitazone or placebo. Myocardial glucose uptake (MGU) and myocardial blood flow (MBF) were measured by positron emission tomography at rest and during adenosine-induced hyperemia during a euglycemic hyperinsulinemic clamp at baseline and after treatment. After 12 weeks, along with a favorable effect on blood lipid parameters, the addition of pioglitazone led to significant improvements in MGU and MBF [42].

Table 44.2 Cardiovascular risk factor reduction with pioglitazone treatment

- Improve dyslipidemia (↑ HDL-C, ↓ TG, ↓ LDL density)
- Decrease microalbuminuria, blood pressure
- Reduce carotid intimal medial thickness
- Reduce neointimal/VSMC (vascular smooth muscle cell) proliferation, macrophage migration
- Improve vascular reactivity, endothelial function
- Decrease vascular inflammation, CRP, Endothelin-1, MMP-9, MCP-1 levels
- Increase thrombolysis, decrease PAI-1 activity
- Increase adiponectin levels

Beneficial effects of pioglitazone on left ventricular (LV) function were seen in a study in 30 nondiabetic, insulin-resistant hypertensive patients. In these subjects, pioglitazone treatment for 6 months increased serum adiponectin levels and insulin sensitivity and also significantly improved LV diastolic function without changes in LV mass [43]. Similar improvements in LV function were seen in another recent study in 15 patients with T2DM where 6 months of pioglitazone treatment improved LV diastolic function and suppressed the synthesis of type III collagen (a marker of myocardial fibrosis). Discontinuation of pioglitazone weakened the suppression of the synthesis of type III collagen and was associated with worse LV diastolic function [44].

Notwithstanding the favorable effects on myocardial blood flow and function mentioned earlier, it must be noted that the use of the TZDs is associated with a propensity towards increased fluid retention and precipitation of congestive heart failure in some patients.

Blood pressure

The prevalence of hypertension in diabetic patients is up to twofold higher than in nondiabetic individuals and in T2DM and other insulin-resistant states there is impaired insulin-induced vasodilatation [45]. It is possible that by improving insulin action, the TZDs enhance the tonic vasodilator response to insulin and thereby reduce peripheral vascular resistance and blood pressure. Further, by reducing hyperinsulinemia and plasma insulin levels, it is possible that the TZDs attenuate the potential blood pressure raising actions of insulin, such as renal sodium retention and increased sympathetic activity [45]. In one study, 60 nondiabetic patients with arterial hypertension were randomized to pioglitazone 45 mg daily or placebo. After 16 weeks, along with significant improvements in insulin sensitivity and lipid parameters, SBP was significantly lower by 6.7 mmHg and DBP by 7.9 mmHg as compared to a decrease of 3.1 and 1.8 mmHg with placebo [46]. In the large PROactive study [47] with 5238 patients, blood pressure over 3 years was reduced significantly more in the pioglitazone-treated group than in the placebo group (median change in SBP 3 mmHg vs. 0 mmHg). Thus although small, the effects of the TZDs on blood pressure are consistent and may be beneficial in the long-term amelioration of cardiovascular complications.

Glomerular function and albuminuria

Microalbuminuria (urinary albumin excretion rate between 30 and 300 mg per 24 h) is widely considered to be a marker of impaired vascular integrity in type 2 diabetic patients and an early indicator of renal and cardiovascular disease risk as well as of an increased risk of all-cause mortality. Studies across populations have demonstrated the ability of the TZDs to reduce urinary albumin excretion. In an early study from Japan [48], 45 type 2 diabetes patients with microalbuminuria were randomly assigned to treatment with pioglitazone 30 mg d^{-1}, glibenclamide 5 mg d^{-1}, or voglibose (an alpha-glucosidase inhibitor) 0.6 mg d^{-1}. After 3 months, only pioglitazone 30 mg daily was effective in reducing urinary albumin excretion and urinary endothelial-1 (ET-1) concentrations. Urinary ET-1 excretion is present in type 2 diabetes patients with microalbuminuria, and an increase in circulating ET-1 precedes the microalbuminuric phase of renal injury related to diabetes. Of note, pioglitazone reduces albuminuria in type 2 diabetic patients with hypertension and microalbuminuria even in the setting of concurrent treatment with renin-angiotensin system inhibitors [49].

In a recent large meta-analysis, treatment with TZDs as compared to placebo and active comparator, was found to significantly decrease urinary albumin and protein excretion in patients with diabetes [50]. Whether this effect is mediated through blood pressure reduction or via direct vasculoprotective mechanisms is not clear at present. Regardless, the TZDs improve blood glucose levels and reduce blood pressure and albumin excretion in patients with T2DM. However, so far, there is no evidence that these short-term benefits translate into favorable effects on hard renal/CVD outcomes in the long term.

Anti-atherogenic effects

Atherosclerosis is a progressive vascular disease initiated by the accumulation of LDL-C in the subintimal space of the vessels and culminating in plaque rupture with resultant thrombosis and acute occlusion leading to a myocardial infarction or stroke. Three key components play a crucial role in the development of accelerated atherosclerosis, the endothelial cells (ECs), the monocyte/macrophage cells and the vascular smooth muscle cells (VSMCs) [51]. All of these major cells express PPARγ and there is a strong evidence from *in vitro* animal and human studies that pioglitazone as a PPARγ agonist has beneficial effects on the endothelium, VSMCs and macrophage function [51,52]. Pioglitazone increases the expression in macrophages of LXRα and ABCA1 (which facilitate the efflux of cholesterol from macrophages and reduces foam cell formation); inhibits VSMC cell proliferation and migration; and improves peripheral and coronary vascular endothelial function in patients with T2DM and CVD.

Thus, the PPAR agonists through their anti-atherogenic effects have the potential to slow the development of/improve the stability of the atherosclerotic plaque. So far the effects of these changes upon biochemical markers and surrogate markers of atherosclerosis progression (like carotid IMT) appear to be

favorable [53,54]. In the CHICAGO study [53], 462 patients with T2DM were randomized to pioglitazone $(15-45\,\text{mg d}^{-1})$ or glimepiride $(1-4\,\text{mg d}^{-1})$ as an active comparator. At week 72, the primary endpoint of progression of mean CIMT was significantly less with pioglitazone versus glimepiride $(-0.001\,\text{mm}$ vs. $+0.012\,\text{mm}$, respectively; difference, $-0.013\,\text{mm}$). Pioglitazone also significantly slowed progression of maximum CIMT compared with glimepiride $(0.002\,\text{mm}$ vs. $0.026\,\text{mm}$, respectively, at 72 weeks; difference, $-0.024\,\text{mm}$). Of note, the beneficial effect of pioglitazone on mean CIMT was similar across pre-specified subgroups based on age, sex, systolic blood pressure, duration of DM, BMI, HbA1c value, and statin use.

Similar vascular beneficial effects of pioglitazone were demonstrated in the PERISCOPE study in which 543 patients with T2DM and CVD underwent coronary intravascular ultrasonography and were randomized to receive glimepiride, $1-4\,\text{mg}$, or pioglitazone, $15-45\,\text{mg}$, for 18 months, with titration to maximum dosage if tolerated [54]. Atherosclerosis progression was measured by repeat intravascular ultrasonography in 360 patients. The main outcome measure of change in percent atheroma volume (PAV) from baseline to study completion increased 0.73% with glimepiride and decreased 0.16% with pioglitazone ($p = 0.002$). Pioglitazone use was also associated with a slightly greater reduction in HbA1c -0.55% versus 0.36% with glimepiride. In the pioglitazone group, HDL-C increased more $(5.7\,\text{mg dL}^{-1}$ vs. $0.9\,\text{mg dL}^{-1}$); and median triglyceride levels were lower by $16.3\,\text{mg dL}^{-1}$ versus an increase of $3.3\,\text{mg dL}^{-1}$ with glimepiride. Hypoglycemia was more common in the glimepiride group, and edema, fractures and decreased hemoglobin levels occurred more frequently in the pioglitazone group. In this study, in patients with T2DM and CAD, treatment with pioglitazone resulted in a significantly lower rate of progression of coronary atherosclerosis compared with glimepiride.

Given the beneficial effects of pioglitazone on surrogate measures of CVD, it is expected that these effects would result in lower cardiovascular morbidity/mortality. This was studied in the PROactive Study in which 5238 patients with T2DM and evidence of pre-existing CVD were randomized to pioglitazone 45 mg daily, or placebo, in addition to their usual glucose-lowering medications [47]. In order to assess the effect of pioglitazone on CAD, independent of its glucose-lowering effects, all patients were treated to optimal glucose, lipid and blood pressure goals. After an average follow up of ∼3 years, pioglitazone treatment was associated with a modest 10% reduction in the risk of the primary composite endpoint of all-cause mortality, nonfatal myocardial infarction, stroke, acute coronary syndrome, and revascularization or amputation ($p = 0.09$). However, the "main secondary endpoint" of all-cause mortality, myocardial infarction, and stroke (defined before the unblinding of the data) was significantly reduced by 16% ($p = 0.027$). Of note, pioglitazone treatment was associated with an increase in congestive heart failure (CHF) and hospitalization for CHF. However, the criteria for heart failure was not clearly

defined and it is unclear whether the frequency of this diagnosis was confounded by an increased presence of peripheral edema in the pioglitazone group. Of note, mortality from heart failure was not increased.

Although the PROactive study results demonstrated a reduction in all-cause mortality, myocardial infarction and stroke with pioglitazone, the study was not designed to determine the mechanism(s) for this benefit. This could have resulted from the lower HbA1c of 0.5% in the pioglitazone group, a small but significant reduction in blood pressure, or changes in the lipid profile. Given the multiple beneficial effects of pioglitazone in improving insulin sensitivity and traditional/nontraditional risk factors, it is tempting to speculate that these anti-atherogeneic effects contributed to the results.

Other potential beneficial nonglycemic effects

Nonalcoholic steato-hepatitis (NASH)
Notwithstanding the fact that troglitazone was withdrawn due to liver toxicity, it does not appear that hepatoxicity is a class effect with PPARγ agonists. On the contrary, the majority of data suggests overall improvement in liver enzymes with pioglitazone use and possible beneficial effects in patients with NASH in whom insulin resistance is a characteristic feature. In a 6-month pilot study in 55 patients with IGT/T2DM and biopsy-confirmed NASH, pioglitazone $45\,\text{mg d}^{-1}$ in conjunction with a hypocaloric diet improved glycemic control and also decreased liver fat content, hepatocyte ballooning/inflammation, and normalized liver aminotransferase levels [55]. In the larger PIVENS study in patients without diabetes, pioglitazone, however, was not superior to placebo for the composite histologic primary endpoint of standardized scores for steatosis, lobular inflammation, hepatocellular ballooning, and fibrosis. However, a post-hoc analysis of patients with well-defined NASH revealed that pioglitazone significantly improved steatosis and inflammation, compared to placebo [56].

Cancer
It is well known that compared with those without diabetes, patients with T2DM are at increased risk of several types of cancer, including a 40% increased risk of bladder cancer [57]. This strong association with cancer is hypothesized to be driven in part by shared risk factors (e.g. age, obesity, smoking) or perhaps by hyperinsulinemia, whereby elevated insulin levels in T2DM stimulate insulin receptors on neoplastic cells and promote cancer growth and division. There is strong evidence that the TZDs through their action on PPARγ receptors in cancer cells suppress the growth of several human cancer lines, *in vitro* and *in vivo* [58], possibly by inhibiting primary tumor growth and metastasis by both direct and indirect anti-angiogenic effects [58]. Recently, however, there is concern that pioglitazone use may be associated with an increased

risk for bladder cancer and the drug has been withdrawn from clinical use in France and Germany. Pioglitazone is still available in the US and other parts of the world, with the warning about the association with bladder cancer [58]. As mentioned previously, interim data from the 8-year follow-up of a Kaiser Permanente study in the US of 193,099 eligible men and women with diabetes mellitus suggest that in the cohort analysis, there is no overall statistically significant increased risk of bladder cancer among patients ever treated with pioglitazone (http://general.takedapharm.com/Trial-Disclosure/01-03-TL-OPI-524-8-year-Interim-Report.pdf).

Polycystic ovary syndrome (PCOS)

PCOS is the most common cause of hyperandrogenemia in women and insulin resistance is a prominent feature of this syndrome. In clinical practice, metformin has been used as an insulin sensitizer in patients with PCOS. However, several studies have documented that the TZDs also have insulin-sensitizing and ovulation-inducing effects in women with PCOS [59]. In a recent meta-analysis of 161 trials, it was found that compared to metformin, pioglitazone was significantly more effective at reducing fasting insulin levels and improving the HOMA-IR index. However, pioglitazone was significantly less effective than metformin at reducing BMI. The effect of pioglitazone on fasting glucose levels, testosterone levels, and clinical measures of hyperandrogenism was no different from that of metformin [59]. Of note, although metformin and pioglitazone improve metabolic and hyperandrogenic parameters, their effects on improving reproductive outcomes is not clear. Given the possibility that pioglitazone may result in ovulation in some premenopausal anovulatory women, caution should be used with pioglitazone in PCOS women.

Inflammation and immunity

In addition to being present in the classic insulin-responsive tissues, PPARγ is also found in other cell types including the white and red pulp of the spleen, human bone-marrow precursors, macrophages/monocytes and colonic epithelium [60]. *In vivo* and *in vitro* studies have shown that the TZDs exert a largely anti-inflammatory effect through several mechanisms including inhibition of proliferation of activated T cells, inhibition of IL-2 secretion and/or the induction of apoptosis, and inhibition of the NF-kappaB pathway [60]. However, one problem in the interpretation of many of the studies of PPARγ effects on inflammation and immunity is that ligands thought to be specific for PPARγ may have regulatory effects on inflammatory parameters that are PPARγ-independent. Recent data suggest that PPARγ is the major functional receptor mediating the common aminosalicylate activities in inflammatory bowel diseases. There is also considerable interest is the recent discovery that some commensal bacteria and natural ligands present in food may induce PPARγ expression and activation in the colon [61].

Dose/drug interactions

Dosage

The usual starting dose for pioglitazone is 15 mg or 30 mg PO once daily [62]. For patients who respond inadequately to the initial dose, the dose can be increased in 15 mg increments up to 45 mg PO once daily. Patients not responding adequately to monotherapy with pioglitazone should be considered for combination therapy with other antidiabetic agents. The safety and efficacy of pioglitazone in adolescents and children has not yet been established. Some authorities recommend limiting pioglitazone to submaximal doses unless there is clear evidence of enhanced efficacy with higher doses in an attempt to minimize the adverse effects of the drug. This approach has not been evaluated in long-term studies.

Drug interactions

Pioglitazone is metabolized by the cytochrome P450 isoform CYP3A4 [62]. Safety and efficacy could be affected when pioglitazone is co-administered with drugs metabolized by this enzyme and blood glucose should be monitored more carefully. Closer blood glucose monitoring is also recommended in patients receiving pioglitazone in combination with CYP3A4 inhibitors like ketoconazole or itraconazole. Strong CYP2C8 inhibitors (e.g. gemfibrozil) increase pioglitazone concentrations and in these patients, the dose of pioglitazone should not exceed 15 mg daily [62]. On the other hand, CYP2C8 inducers (e.g. rifampin) may decrease pioglitazone concentrations. If an inducer of CYP2C8 is used during treatment with pioglitazone, changes in diabetes treatment may be needed based on clinical response without exceeding the maximum recommended daily dose of 45 mg.

Since pioglitazone is metabolized by CYP3A4, it is possible that poglitazone may reduce the bioavailability of oral contraceptives containing ethinyl estradiol and norethindrone by induction of CYP3A4 and reduce the effectiveness of these agents. Caution should be exercised in these patients and alternative methods of contraception should be recommended.

Monitoring requirements/precautions/contraindications

Renal impairment

Renal elimination of pioglitazone is negligible, and the drug is excreted into the bile either unchanged or as metabolites and eliminated in the feces. No dose adjustment in patients with renal impairment is required [62].

Hepatic impairment

Patients with T2DM often have ALT elevations due to fatty liver disease or cardiac disease with episodic congestive heart failure. Hence, LFTs should be obtained before starting pioglitazone. In patients with abnormal liver tests, pioglitazone should be

initiated with caution. In patients with serum ALT greater than three times the reference range with serum total bilirubin greater than two times the reference range without alternative etiologies, pioglitazone should not be started since these patients are at risk for severe drug-induced liver injury. In addition, LFTs should be measured whenever clinically indicated [62].

Congestive heart failure (CHF)

Although most patients tolerate TZD treatment well, some patients will develop clinically significant edema. Experience from clinical trials indicate that there is a small expansion in plasma volume associated with TZD use which might result in edema occurring in the peripheral interstitial space [62]. In susceptible patients, the edema starts early, usually within several weeks, and is mild. Occasionally, it can be severe with rapid weight gain. Although the fluid accumulation usually occurs in the lower extremities, it may be seen throughout the body and rarely even precipitate pulmonary edema [62].

Based on the above, pioglitazone should be used with caution in patients with pre-existing edema, especially in those who have milder degrees of heart failure (NYHA Class 1 and 2) [62]. In patients with NYHA Class 3 and 4 cardiac status, treatment with pioglitazone is not recommended. In all other patients, pioglitazone therapy should be initiated with a low dose and patients should be evaluated early for edema (within several weeks). If edema does occur, dose reduction may be attempted. In those who develop symptoms of CHF, however, it may be prudent to discontinue the drug altogether, since in the published case reports of pulmonary edema, clinical improvement did not occur with diuretics and inotropes, while the TZD agent was still continued. In those with peripheral edema who do not respond to conventional doses of diuretics, it may be wise to discontinue the TZD agent permanently and use other oral agents or insulin. There is evidence that diuretics acting in the distal collecting ducts such as hydrochlorothiazide and spironolactone may mitigate the fluid retention associated with glitazone therapy, whereas proximally acting furosemide does not [63].

Side effects

Pioglitazone has now been in clinical use worldwide with several million patients treated for several years. The vast majority of these patients have tolerated these agents well and have shown clinical improvement in their glycemic status. During double-blind clinical trials, the most frequently reported adverse reactions in pioglitazone-treated patients were headache, hyperglycemia, myalgia, pharyngitis, sinusitis, tooth disorder, and upper respiratory tract infection [62]. Overall, the types of adverse experiences reported when pioglitazone was used either as monotherapy or in combination with sulfonylureas, metformin, and insulin were similar to placebo, except

for hypoglycemia and edema. Importantly, the incidence of withdrawals from clinical trials due to an adverse event other than hypoglycemia was similar for patients receiving placebo or pioglitazone.

Edema

In clinical trials and postmarketing surveillance, the incidence of edema has varied from about 3% to 7.5% with the TZDs compared to 1% to 2.2% with placebo or other oral antidiabetic agents [64]. Of note, the highest incidence of edema has been reported when pioglitazone is used in combination with insulin. In controlled clinical studies, edema occurs in 15.3% in those treated with insulin+pioglitazone compared to 7.0% in insulin+placebo-treated patients. In a small minority of patients, the TZDs lead to significant peripheral edema and in some patients a precipitation/worsening of CHF [64].

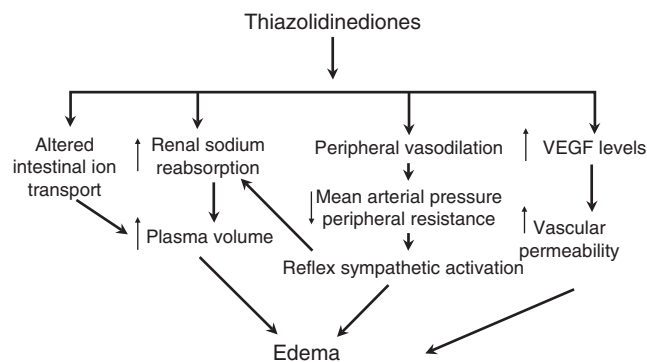
It is still not clear by what precise mechanism(s) the TZDs cause edema or whether the edema is related to decompensation of cardiac function [64]. In early studies in nondiabetic volunteers, the TZDs were found to increase plasma volume by about 6–7% [64]. Whether it is this increase in plasma volume that leads to edema or other causes such as increased renal tubular sodium reabsorption, reflex sympathetic activation, alteration of intestinal ion transport, or increased production of VEGF (a potent tissue permeability factor) is still not clear (Figure 44.4). In rodent models, renal collecting duct-specific deletion of the PPARγ receptor has been shown to block TZD-induced fluid retention. In a recent study in obese patients with T2DM and poor glycemic control, it was noted that intensification of insulin therapy alone and the addition of pioglitazone both significantly improved glycemia (HbA1c 7.8 to 7.2% and 7.6 to 7.1%) and increased body weight (1.7 and 4.9 kg, respectively) [65]. Despite the greater weight gain with the addition of pioglitazone, the increase in body water was similar in both groups 1.6 versus 1.7 L. However, the increase in total body water was mainly extracellular and interstitial with pioglitazone compared with intracellular increase with insulin therapy alone. Pioglitazone also increased the filtered


Figure 44.4 Multifactorial mechanisms of edema formation with thiazolidinediones.

load of sodium reabsorbed at the distal nephron with no net change in the fractional excretion of sodium. The authors speculated that since TZD treatment (possibly through a PPARγ effect) may cause increased collecting duct reabsorption of sodium, this potential edema-causing effect may be offset by decreased proximal-tubular reabsorption of sodium. Those diabetics who do not have this potential renal compensatory mechanism may be more prone to develop fluid accumulation and heart failure. As mentioned previously, fluid retention may be minimized by co-administration of thiazide diuretic or spironolactone. The recent development of partial PPARγ agonists with potent antidiabetic activity, but no fluid retention, weight gain or bone loss properties is a promising development in this field [11].

Weight gain

In clinical studies, pioglitazone treatment has been accompanied by weight gain in a dose-related manner [62]. The change in average weight in US placebo-controlled monotherapy trials ranged from 0.5 kg to 2.8 kg for pioglitazone-treated patients compared to a weight loss of 1.3 kg to 1.9 kg in placebo-treated patients. In combination with a sulfonylurea, the change in average weight was 1.9 kg and 2.9 kg for 15 mg and 30 mg of pioglitazone, respectively, and −0.8 kg for placebo. In combination with metformin, the increase in average weight was 1.0 kg for 30 mg of pioglitazone versus −1.4 kg for placebo. The change in average weight in combination with insulin was 2.3 kg and 3.7 kg for 15 mg and 30 mg of pioglitazone, respectively, and no weight change for placebo. It is also important to note that thiazolidinedione-induced weight gain is due to a combination of fluid retention and adipose tissue accumulation. As discussed earlier [65], the increase in total body water was mainly extracellular and interstitial with pioglitazone compared with intracellular increase with insulin therapy alone. Also, with pioglitazone, there is an increase in the subcutaneous adipose tissue compartment and lean body mass along with a trend towards a decrease in visceral adipose tissue [41].

Bone fractures

Data from *in vitro* and rodent studies demonstrate that PPARγ activation inhibits bone formation by diverting mesenchymal stem cells from the osteogenic to the adipocytic lineage and also possibly by increasing bone resorption secondary to stimulating osteoclast development. PPARγ agonists may also have indirect adverse skeletal effects through modulation of circulating hormones/cytokines known to influence bone metabolism [66]. In the PROactive study [47], the incidence of bone fracture in females was 5.1% for pioglitazone versus 2.5% for placebo. This difference was noted after the first year of treatment and persisted during the course of the study. The majority of fractures in female patients were nonvertebral (lower limb and distal upper limb). No increase in the incidence of fracture was observed in men. The risk of fracture should be considered in the care of patients, especially female patients, treated with pioglitazone and attention should be given to assessing/maintaining bone health per current standards of care.

Anemia

It is well documented that the TZDs increase plasma volume and due to a dilutional effect, there will be decreases in hemoglobin. This has been shown to occur in a dose-related fashion in patients treated with pioglitazone alone or in combination [62]. These changes occur primarily during the first 4–12 weeks of therapy and remain relatively constant thereafter and are not associated with any significant hematologic clinical effects. In US double-blind studies, anemia was reported in 0.3 to 1.6% of pioglitazone-treated patients and 0 to 1.6% of placebo-treated patients in monotherapy and combination studies [62].

Hypoglycemia

The TZDs do not stimulate insulin secretion and hence when used as monotherapy, are not expected to cause hypoglycemia. However, hypoglycemia has been reported during combination therapy with sulfonylureas or insulin [62]. Hypoglycemia was reported for 1% of placebo-treated patients and 2% of patients receiving pioglitazone in combination with a sulfonylurea. In combination with insulin, hypoglycemia was reported for 5% of placebo-treated patients, 8% for patients treated with pioglitazone 15 mg, and 15% for patients treated with pioglitazone 30 mg.

During required laboratory testing in the pioglitazone clinical trials, sporadic, transient elevations in creatine phosphokinase levels without symptoms were observed [62]. These elevations resolved without any apparent clinical sequelae and the relationship of these events to pioglitazone therapy is unknown.

Future developments

Given the unfavorable side-effect profile of the TZDs, there has been considerable interest in developing PPAR agonists with glucose-lowering/insulin-sensitizing PPARγ agonist properties of the TZDs and the lipid-modifying PPARγ properties of fibrates along with an improved safety profile.

Conclusion

The introduction of the PPARγ agonist thiazolidinediones heralded a new era in the treatment of patients with T2DM. These agents exert direct effects on the mechanisms of insulin resistance which is a major pathophysiologic abnormality in T2DM. As highly selective and potent PPARγ agonists, the TZDs regulate the expression of numerous genes that affect carbohydrate/lipid metabolism and vascular function. This results not only in lower blood glucose levels and improved glycemia, but also amelioration of several components of

the insulin-resistance syndrome including dyslipidemia, hypertension, and endothelial dysfunction which untreated lead to accelerated atherosclerosis and premature cardiovascular morbidity/mortality in patients with T2DM. However, these beneficial effects have not translated into clear-cut cardiovascular benefits. Today, pioglitazone is the only agent in this class that is widely available in the US and most of the world. Pioglitazone treatment improves insulin sensitivity and glycemic/lipid parameters and also has favorable effects on diabetes prevention. In one study, pioglitazone reduced the composite secondary outcome of all-cause mortality, nonfatal myocardial infarction, and stroke in patients with T2DM and high CVD risk. However, pioglitazone use has been limited by concerns about weight gain, bone loss, fluid retention, edema, and a recent association with increased bladder cancer risk. Despite this, the PPARγ agonists still have a role in the treatment of T2DM, since this is the only class of drugs that primarily targets insulin resistance. Also, these drugs can be used in patients with renal impairment and exhibit a low incidence of hypoglycemia. In the future, it is possible to envisage the availability of tailored PPAR agonists which through their selective effects will have enhanced beneficial effects on glucose, lipid and vascular endothelial metabolism without the unwanted side effects of weight gain and fluid retention.

Key points

- Alpha-glucosidase inhibitors reduce postprandial plasma glucose rise by delaying glucose absorption by the small intestine.
- Alpha-glucosidase inhibitors are effective in improving HbA1c whether they are prescribed as monotherapy or in combination with other antidiabetic medications.
- The major side effects of alpha-glucosidase inhibitors are gastrointestinal in the form of flatulence, abdominal cramps and rarely diarrhea; these side effects can be minimized by the "start low go slow" policy.
- Acarbose and voglibose have been shown to be effective in reducing the risk of diabetes in subjects with IGT.
- Studies have suggested that acarbose could reduce the risk of cardiovascular disease in subjects with IGT and type 2 diabetes mellitus.
- Alpha-glucosidase inhibitors have an excellent safety profile.

Introduction

Dietary and lifestyle interventions still remain the cornerstone in the treatment of patients with type 2 diabetes mellitus (T2DM). However, when diet and physical exercise fail to achieve optimal glycemic control, oral hypoglycemic agents must be added. Most of these agents have been shown to decrease fasting plasma blood glucose, but postprandial hyperglycemia persists in more than 60% of patients, accounting in part for the sustained increase in HbA1c [1]. It has been suggested that postprandial glycemic excursions contribute to the development of diabetes-specific complications (i.e., retinopathy and nephropathy) and, based on epidemiologic studies, could also be involved in the development of macrovascular complications [2,3].

Slowly absorbable carbohydrates and high-fiber diets blunt the postprandial increase in plasma glucose and insulin levels. Most patients, however, find these regimens difficult to follow. The α-glucosidase inhibitors (AGI) specifically delay the digestion of complex carbohydrates and decrease the postprandial rise in plasma glucose, thus reproducing the effect of a low glycemic index/high-fiber diet. These drugs significantly reduce postprandial glycemic and insulinemic excursions whether they are used as monotherapy or in combination for the treatment of T2DM and also in T1DM. These drugs can be associated with gastrointestinal symptoms but have an excellent safety profile.

Mechanism of action

α-Glucosidase inhibitors competitively block small intestine brush border α-glucosidases that are necessary to hydrolyze di-, oligo-, and polysaccharides to monosaccharides for absorption [4]. Normally, carbohydrates are primarily and rapidly absorbed in the first half of the small intestine. With AGI, carbohydrate absorption and digestion occur throughout the small intestine, resulting in a slower absorption and a blunting of the postprandial rise in plasma glucose [5].

Three AGI have been developed (acarbose, miglitol, and voglibose) with similar pharmacologic profiles (Figure 45.1) [6,7]. Acarbose, a pseudotetrasaccharide of microbial origin, is structurally analogous to an oligosaccharide derived from starch digestion. It is made up of a maltose unit linked to an acarviosine unit, which represents the active part of the molecule [5]. The acarviosine unit has nitrogen linkage, which is responsible for its high affinity for the carbohydrate-binding site of various α-glucosidases, and exceeds the affinity (10- to 100,000-fold) of regular oligosaccharides from nutritional carbohydrates [4]. Because of this C-N linkage, acarbose cannot be cleaved and, therefore, enzymatic hydrolysis is blocked [4]. Despite its high affinity for these enzymes, acarbose binding is reversible, and its inhibition kinetic is competitive. Owing to
Figure 45.1 Structural formula of the α-glucosidase inhibitors acarbose, miglitol, and voglibose.

its specificity for α-glucosidases, β-glucosidases (e.g. lactases) are not inhibited by acarbose, and therefore lactose absorption is not affected. Intestinal glucose absorption is also not affected [4]. Because less than 1–2% of the active compound is absorbed, acarbose displays its inhibitory activity throughout the small intestine up to the ileum [4]. Acarbose is cleaved in the large intestine by bacterial enzymes into several metabolizable intermediates and 4-methylpyrogallol derivatives. Thus even though acarbose itself is poorly absorbed, 35% of an oral dose appears as metabolites in the urine [8].

Chemically, miglitol closely resembles the glucose molecule and is significantly absorbed through a jejunal transport mechanism identical to that for glucose. It then circulates and concentrates in enterocytes of the small intestine where it competes for the α-glucosidases. It is not metabolized and is excreted quantitatively by the kidney [8].

Voglibose is an N-substituted derivative of valiolamine, a branched-chain aminocyclitol isolated from the fermentation broth of *Streptomyces hygroscopicus*, subspecies limoneus. Its N-substituted moiety is derived from glycerol. Voglibose is poorly absorbed by the gastrointestinal tract and hardly metabolized [9].

To be efficient, AGI must be present at the site of enzymatic action at the same time as the polysaccharides, oligosaccharides, or disaccharides. Therefore, they should be taken with the first bite and not more than 15 min after the beginning of the meal [10].

Clinical efficacy of α-glucosidase inhibitors

Treatment of diabetes mellitus
Much experience has been gained with AGI in the treatment of diabetes mellitus. The benefit of adding them to the diet alone or in combination with other oral agents, as well as with insulin in type 2 or type 1 diabetic patients has been investigated in numerous randomized, double-blind, placebo-controlled trials, as well as open-labeled controlled studies, and postmarketing surveillance trials.

In a Cochrane systematic review of 22 placebo-controlled studies ($n = 2238$), acarbose showed a significant reduction in postprandial plasma glucose (PPG) of -2.32 mmol L^{-1} (95% CI -2.73, -1.92) as well as in fasting blood glucose (FBG) of 1.09 mmol L^{-1} (95% CI -1.36, -0.83) (28 studies, $n = 2838$) [11]. Through their effects on FBG and PPG, AGI significantly impact on HbA1c. Multiple studies have shown that the decline usually ranges from 0.5 to 1.5% (Figure 45.2). In fact, the results of the same Cochrane meta-analysis of 28 studies comparing the effect of acarbose versus placebo showed a decline in HbA1c of 0.77% (95% CI -0.9%, -0.64%). The total effect of miglitol versus placebo in seven studies was a decline of 0.68% (95% CI -0.93%, -0.44%) [12]. Few large-scale studies have been done with voglibose, but when added to current treatment, results show a mean HbA1c reduction of 0.31% [13–18].

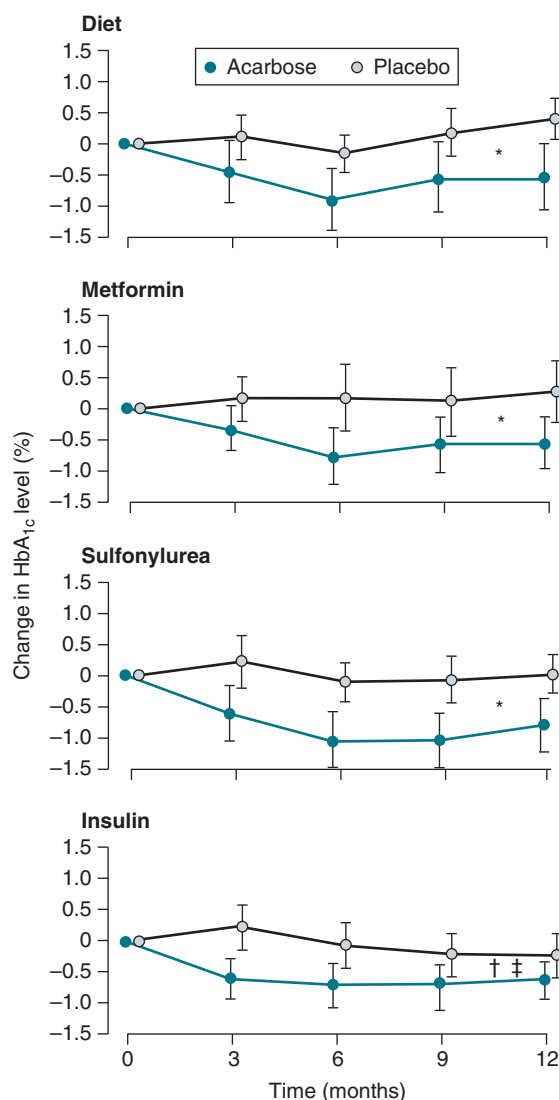
Large, controlled or open trials have revealed a number of constant features associated with acarbose therapy in


Figure 45.2 Effects of acarbose and placebo on HbA1c levels throughout the 1-year study period in groups of patients treated with diet alone, metformin, sulfonylurea, or insulin. Data are expressed as means with 95% CI. *$p \leq 0.010$, †$p = 0.077$. p values represent differences between changes from baseline (time 0) to endpoint (time 12 months) for acarbose and placebo. ‡$p = 0.01$ by covariance analysis. diabetes [19–21]. The glucose-lowering effect is observed from the first week of therapy, and is maintained throughout the treatment period, even after 5 years. Acarbose efficacy is present whatever the current treatment. However, a greater response to treatment has been reported in patients with recently diagnosed diabetes and/or naïve to oral hypoglycemic agents. The drug is effective independent of sex or ethnicity. No weight gain occurs and most studies have shown small but consistent weight loss. Used as monotherapy, there is no risk of hypoglycemia. The main cause of treatment discontinuation is gastrointestinal side effects, with discontinuation rates varying from 2 to 40%. However, very few serious adverse effects are associated with AGI, making it a particularly safe drug.

Dose–response relationship

The dose–response relationship has been shown, mostly with acarbose, in large multicenter trials at dosages ranging from 25 to 300 mg three times daily. Overall, these trials indicate that the 100 mg three times daily dose evokes a near maximal response [22,23].

Efficacy of α-glucosidase inhibitors combined with diet therapy in patients with type 2 diabetes

Major randomized controlled trials, up to 5 years' duration, including type 2 diabetic patients insufficiently controlled by diet alone, have tested AGI versus placebo [11,19,20,22–25]. Overall, these studies confirmed the efficacy of AGI, showing a mean reduction of 0.66% in HbA1c, a 1.03 mmol L^{-1} decline in FBG, and a 2.6 mmol L^{-1} fall in PPG.

A small study with patients newly diagnosed with T2DM compared the effects of dietary treatment alone or with the addition of voglibose on abdominal visceral adipose tissue area (VAT) and subcutaneous adipose tissue area (SAT). Voglibose showed better results for both parameters after only 3 months of treatment. In the diet group, changes in VAT were of 27.7 ± 20.1 cm^2 compared to 39.4 ± 20.4 cm^2 in the voglibose group. For the SAT, changes of 20.9 ± 21.8 cm^2 were observed for the diet group versus 29.3 ± 32.8 cm^2 for voglibose [17].

Efficacy of α-glucosidase inhibitors in comparison to sulfonylureas or metformin

Ten studies have compared AGI head to head with sulfonylureas in patients with T2DM inadequately controlled on diet alone [26–34]. AGI appeared to be less potent, with a mean adjusted HbA1c reduction of 0.74% versus 1.18% with sulfonylureas.

Few studies have compared AGI with metformin in patients failing dietary treatment. In a study by Hoffman and Spengler, acarbose (300 mg d^{-1}) had the same efficacy as metformin (1700 mg d^{-1}), with a mean HbA1c reduction of 1%. Chiasson et al. showed that miglitol (300 mg d^{-1}) had a lower efficacy (HbA1c -0.4%) than metformin (1500 mg d^{-1}; HbA1c −1.2%) [24], but there was a synergism effect when combining miglitol with metformin (HbA1c −1.8%).

Efficacy of α-glucosidase inhibitors as an adjunct treatment to sulfonylurea and/or metformin

A number of studies have tested acarbose and miglitol as add on therapy in type 2 diabetic patients inadequately controlled with sulfonylureas [19,20,26,30,35–39]. When added to sulfonylurea therapy, HbA1c was decreased by an adjusted mean of 0.81%, FBG by 1.1 mmol L^{-1}, and PPG by 2.25 mmol L^{-1}. In patients previously treated with sulfonylureas, the benefit of acarbose

seemed comparable to the addition of metformin for lowering HbA1c [36,39].

In type 2 diabetic patients suboptimally controlled with metformin, the addition of acarbose produced a mean reduction of 0.85% in HbA1c, 1.36 mmol L^{-1} in FBG, and 2.76 mmol L^{-1} in PPG [19,20,40–43].

When combined sulfonylurea and biguanide therapy failed to achieve adequate metabolic control, the addition of acarbose resulted in a similar reduction in mean HbA1c of 0.81% [19,44–48]. In a large open trial, diabetic patients failing with a combination of sulfonylurea and biguanide had a much smaller HbA1c benefit than did patients treated previously with a single oral hypoglycemic agent [21].

Thiazolidinedione and α-glucosidase inhibitors

Few data are available for this combination. In one study, 274 patients on sulfonylurea and metformin were randomized to either pioglitazone or acarbose. Patients were followed for 9 months. The reduction in HbA1c was greater in the group treated with pioglitazone (−1.4 vs. −0.9%) but weight gain was also significantly higher (+1.4 kg vs. −1.2 kg) [45]. Likewise, a study of 60 patients randomized to either pioglitazone or voglibose for 6 months showed a slightly better performance on HbA1c in the pioglitazone group (−0.3 vs. −0.2%). However, no change in BMI or waist circumference was observed with pioglitazone, whereas these parameters significantly decreased with voglibose (−1.2 kg m^{-2} in BMI and −3 cm in waist circumference) [49].

Efficacy of α-glucosidase inhibitors in comparison to dipeptidyl peptidase-4 inhibitors

The dipeptidyl peptidase-4 inhibitors (DPP-4 inhibitors) alogliptin, vildagliptin, sitagliptin, and linagliptin have been compared to voglibose or acarbose in a few double-blind randomized trials ($n > 2200$). Overall, the mean adjusted HbA1c reduction was of 0.54% in the AGI groups versus 0.9% in the DPP-4 inhibitor groups [14–16,50]. Both therapies are associated with a low hypoglycemic risk.

Efficacy of α-glucosidase inhibitors in insulin-treated type 2 diabetic patients

The addition of bedtime insulin is a frequent option for patients with T2DM insufficiently controlled with diet, exercise, and maximum tolerated doses of two or three oral hypoglycemic agents. The addition of acarbose has been compared to the introduction of bedtime NPH. Although acarbose resulted in improvement of metabolic control compared to placebo (HbA1c −0.8% vs. −0.2%), it was less effective than insulin (HbA1c −2.3%) [51]. Therefore, this strategy is generally considered as a compromise for patients who refuse insulin injections.

When acarbose was combined with insulin therapy, however, it resulted in significant metabolic improvement, with a mean adjusted reduction in HbA1c of 0.5% without any effect on insulin dosages but also without any weight gain [20,23,52–55].

Comparative studies between α-glucosidase inhibitors

Few studies have compared the different AGI amongst themselves. In nondiabetic subjects, voglibose seemed slightly less potent than acarbose, with no difference in side effects [7]. Miglitol gave softer stool and slightly less flatulence than acarbose [56]. In type 2 diabetic patients, voglibose was associated with less gastrointestinal side effects than acarbose, but was also less effective in reducing PPG excursion [6,57].

Benefits of α-glucosidase inhibitors in elderly patients

Because of its mechanism of action and safety profile, acarbose could be an interesting first-line drug for elderly type 2 diabetic patients because of the low hypoglycemic and drug interaction risks [5,25,30,58].

Furthermore, postprandial hypotension is an important clinical problem and has been recognized as a common cause of syncope and falls in the elderly population [59,60]. Interestingly accumulating data support the usefulness of AGI in attenuating this phenomenon. In fact, many studies and case reports have shown that these drugs reduce, sometimes markedly, the postprandial hypotensive response to carbohydrate intake in nondiabetic patients [61–63] and in type 2 or type 1 diabetic patients suffering from this problem [64].

Many mechanisms have been proposed, one of which is the effect of AGI on carbohydrate absorption. In fact, by slowing the rate of absorption, the acute rise in splanchnic blood flow is blunted [63].

Furthermore, constipation is often a major problem in this population, and so gastrointestinal side effects reducing colonic transit time may in some circumstances be perceived here as an advantage [30,65].

Impaired glucose tolerance and prevention of type 2 diabetes

The STOP-NIDDM trial has investigated the potential of acarbose in preventing or delaying the development of T2DM in subjects with impaired glucose tolerance (IGT). A total of 1429 subjects were randomized to acarbose or placebo. On the basis of a single OGTT (oral glucose tolerance test), acarbose reduced the risk of developing T2DM by 25% [66] (Figure 45.3). If two positive OGTTs were used to confirm the diagnosis of T2DM as recommended by the WHO (World Health Organization) and the Expert Committee of the ADA (American Diabetes Association), the relative risk reduction was 36.4%. The beneficial effect of acarbose was independent of age, sex, and BMI. The STOP-NIDDM trial also showed that acarbose treatment was additionally associated with a significant increase in the reversion of IGT to normal glucose tolerance. These results indicate that 11 patients should be treated for 3.3 years to prevent or delay one case of T2DM. However, those who had the metabolic syndrome (MS) (61%) had a higher risk of progressing to diabetes, but were also more responsive to acarbose; in fact, only
Figure 45.3 Effect of acarbose on the cumulative incidence of diabetes in the STOP-NIDDM trial. Source: Adapted from Chiasson et al. [66]. Reproduced with permission of Elsevier.

5.8 patients with prediabetes and the MS had to be treated to prevent one case of diabetes, an efficacy similar to that of lifestyle modification [67]. Acarbose treatment was also associated with a significant reduction in the incidence of macrovascular events and new cases of hypertension, two prespecified secondary endpoints (Figure 45.4) [68]. Thus, in subjects with IGT, acarbose is effective in decreasing the risk of diabetes and hypertension, and potentially, cardiovascular complications [68,69].

Similarly, a multicenter randomized, double-blind trial was performed in 1780 patients with IGT, randomly assigned to receive either voglibose or placebo [70]. Because of the highly significant reduction in the incidence of diabetes in the voglibose group, the study was discontinued prematurely after a mean duration of 48.1 weeks. Voglibose treatment was associated with a 40.5% reduction in the risk of developing T2DM compared to placebo (HR 0.595; 95% CI 0.433–0.818; $p = 0.0014$). Voglibose also increased the conversion of IGT to normal glucose tolerance (HR 1.539; 95% CI 1.357–1.746; $p < 0.0001$). Therefore, as with acarbose, voglibose is effective in decreasing the risk of diabetes in subjects with IGT.

The effect of AGI on the prevention of T2DM is very similar to that of metformin (31%) [71]. Lifestyle intervention, however, was more effective in reducing the risk of progressing from IGT to diabetes (58%) [71,72]. On the other hand, the thiazolidinediones, rosiglitazone and pioglitazone, were more effective than lifestyle (60% and 72%, respectively), but because of their adverse effects, will very unlikely be recommended for the prevention of diabetes [73,74].

Efficacy of α-glucosidase inhibitors in type 1 diabetic patients

α-Glucosidase inhibitors have been tested in patients with T1DM. These trials have shown acute and chronic reductions of PPG. In long-term treatment, eight published trials including 471 patients showed a mean adjusted HbA1c decrease of 0.54%

Patients at risk														
Acarbose	659	635	622	608	601	596	590	577	567	558	473	376	286	203

when acarbose was added to regular human insulin [75–78]. In most studies, acarbose improved the plasma glucose profile with lowered postprandial plasma glucose excursion and delayed nadir values [79,80]. Studies have also shown that when AGI are added to regular insulin, there is a decrease in the risk of nocturnal and daytime hypoglycemia as well as during postprandial exercise [80,81]. Though acute studies have shown an insulin-sparing effect of acarbose (approximately 30%), especially for pre-meal insulin requirements [75,79,82], the largest placebo-controlled trial in patients with T1DM could not confirm this sparing effect after 24 weeks of treatment [78]. The usefulness and the interests of the addition of AGI in T1DM have disappeared since the rapid-acting insulin analogues have become available.

Other effects of α-glucosidase inhibitors

Gastrointestinal peptide secretion

α-Glucosidase inhibitors modify the secretion of gastrointestinal peptides, such as glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide 1 (GLP-1). When the AGI are taken with a meal rich in carbohydrates, GIP secretion is decreased while GLP-1 is markedly increased, especially in the late postprandial period [8,82–85]. Whether these effects on GIP and GLP-1 play a role in the therapeutic effect of AGI is unclear.

Cardiovascular risk factors

In animal models of diabetes and/or dyslipidemia, AGI reduce serum triglycerides in a dose-dependent manner. In humans, acarbose was shown to lower the postprandial triglyceride rise [40,86,87] but its effect on fasting levels has been inconsistent with most studies reporting a small but significant reduction [28,39,40,75,86,88–93].

The effects of AGI on fasting total cholesterol and HDL cholesterol appear to be minor or marginally significant [18,21, 88,89,93]. The reported changes may reflect modifications in glycemic control more than a direct action of the drug [8].

Because of their effect on PPG and insulin excursion, AGI have been shown to decrease insulin resistance in most [25,58,66,94–97) but not all studies [98–100]. The negative results in the latter studies may be related to the very poor glycemic control.

Acarbose has been shown to have a favorable effect on blood pressure. Hanefeld et al. performed a meta-analysis of seven randomized, double-blind, placebo-controlled acarbose trials, for a total of 2180 type 2 diabetic patients, measuring the effects of acarbose on metabolic parameters as well as cardiovascular events [101]. Treatment duration varied from 52 to 164 weeks. The overall analysis revealed that systolic blood pressure was significantly lowered by 2.7 mmHg ($p = 0.024$) with acarbose treatment. Furthermore, data from the STOP-NIDDM trial indicate that acarbose could delay the appearance of new cases of high blood pressure in IGT patients [68].

Acarbose has been shown to have a neutral or a lowering effect on body weight. Two different studies could not show any effect of acarbose on energy intake, nutrient intake, or dietary patterns [102,103]. Theoretically, carbohydrate malabsorption associated with acarbose could produce weight loss. However, carbohydrates that reach the colon are metabolized by bacteria into short chain fatty acids which are then absorbed, resulting in no or minimal caloric loss. In general, clinical trials with acarbose found no [19,104] or small (~1 kg) weight loss after 24 weeks to 5 years of treatment [6,21,28,36,40,44,50,66,102,105]. Overall, AGI exert neutral or slightly favorable actions on different cardiovascular risk factors that are part of the metabolic syndrome: excess body weight, high blood pressure, postprandial hyperlipemia, and insulin resistance.

Potential effects of α-glucosidase inhibitors on the prevention of long-term diabetic complications

Data from animal studies suggest that acarbose has significant beneficial actions on microvascular complications [106]. All studies indicate that the positive effects are through its influence on glycemic control. Studies in different animal models of diabetes have shown that acarbose successfully reduces or prevents renal abnormalities, eye problems, and neuropathy associated with diabetes [106].

Finally, there is rising evidence that acarbose could be useful in reducing macrovascular complications associated with diabetes [106]. In a rodent model (the LA-corpulent rat), 8 months of acarbose treatment led to a significant regression in myocardial lesions. Similar findings on aortic atherosclerosis have been obtained in a rabbit model fed an atherogenic diet.

Carotid artery intima-media thickness (IMT) is generally accepted as a surrogate for atherosclerosis and is recognized as an independent predictor of coronary heart disease and stroke [107]. Since postprandial hyperglycemia has been associated with increased common carotid IMT [108,109], much interest has emerged regarding the potential effect of an AGI on this surrogate measurement. Five recent randomized controlled trials of at least 1 year duration studied the progression of carotid IMT with an α-glucosidase inhibitor in comparison to a placebo, no treatment or other hypoglycemic agents, in 411 patients with IGT or T2DM [18,88,89,104,110]. All five studies were associated with a significant decrease in the annual progression of carotid IMT when treated with one of the AGI, suggesting an anti-atherosclerotic effect in humans.

In the STOP-NIDDM trial, acarbose treatment in subjects with IGT was associated with a 49% reduction in cardiovascular events [68]. This was further supported by a meta-analysis of seven randomized, double-blind, placebo-controlled acarbose trials in patients with T2DM treated from 52 to 164 weeks ($n = 2180$) [101]. The analysis showed a highly significant relative risk reduction of 35% for any cardiovascular event in the acarbose-treated group.

However, it is still debated whether the reduction in cardiovascular events associated with AGI treatment in subjects with IGT or diabetes is a cause-and-effect relationship as suggested by the STOP-NIDDM trial and the MeRIA meta-analysis [3,68]. It is hoped that the question will be answered by the Acarbose Cardiovascular Evaluation (ACE) trial, a double-blind, randomized, multicenter, cardiovascular intervention study currently in progress. In this study, 7500 patients with IGT and coronary heart disease are randomized to either acarbose or placebo and followed for a minimum of 4 years. The primary objective is to determine whether reducing postprandial hyperglycemia with acarbose can reduce cardiovascular-related morbidity and mortality [111].

The exact mechanisms by which PPG could contribute to diabetic vascular complications are still being studied. Nonetheless, there is a growing literature suggesting that the generation of reactive oxygen species may be the common pathway [112,113] triggered by acute hyperglycemia resulting in oxygen stress, subclinical inflammation, activation of procoagulation factors and endothelial dysfunction, the first step to atherosclerosis. The combination of all these atherogenic mechanisms could potentially cause CVD [114].

Treatment of reactive hypoglycemia

On the basis of their pharmacology, AGI can be useful in the treatment of reactive hypoglycemia and/or dumping syndrome in nondiabetic patients [8,115,116].

Tolerability of acarbose

Thousands of patients have been treated with this medication for several years without any major adverse effects (Table 45.1); acarbose is a safe drug [8].

Gastrointestinal side effects

The main side effects of treatment are gastrointestinal symptoms consisting of abdominal distention, flatulence, diarrhea, and borborygmus in approximately 50% of patients. These adverse events are related to intracolonic fermentation and the consequent gas production of carbohydrates not absorbed in the small bowel. The symptoms are usually mild to moderate and tend to decrease with continued treatment [22,25]. With time, the α-glucosidases of the distal small intestine will be activated, and more carbohydrates will be digested and absorbed distally, reducing the spill over into the large bowel. That is why starting with a low dose and increasing it slowly can help minimize the side effects [8,66]. The importance of a "start low go slow" strategy is confirmed by the positive relationship between higher initial doses and higher discontinuation rates.

There is no correlation between carbohydrate intake, fiber content of the diet or meal pattern (regular vs. irregular) and side effects associated with acarbose [117].

The treatment discontinuation rate, close to 25% in most large trials, is mostly related to gastrointestinal side effects [20,24,66]. Some studies including the UKPDS have reported much higher discontinuation rates (~40%) [8,19]. However, others have found a much lower rate of patients unable to tolerate AGI which is comparable to that observed with biguanides (i.e., 5–7%) [22,24,36,118]. No clear explanations are available for such discrepancies, but false evaluation of the gastrointestinal side effects can lead to unnecessary gastroenterologist consultations.

Despite these gastrointestinal symptoms, the quality of life of patients on acarbose has been shown to be as good as, if not better, than with sulfonylurea or insulin therapy [25].

Hypoglycemia

Acarbose monotherapy does not cause hypoglycemia [19]. However, it may potentiate the hypoglycemic action of sulfonylureas and insulin. A reduction in dosage of concomitant hypoglycemic agents may be necessary when acarbose is introduced. However, if a patient taking acarbose experiences hypoglycemia, it is recommended that it should be treated with glucose since the absorption of sucrose and complex carbohydrates could be delayed by the drug.

Table 45.1 Comparison of adverse effects of different available antidiabetic oral agents

Adverse effect	Sulfonylureas	Metformin	Thiazoles	Acarbose	DPP-4 inhibitors
Weight gain	+	−	+/++	−	−
Hypoglycemia	+/++	−	−	−	−
Hypersensitivity reactions	+	−	+	−	+
Drug interactions	+	−	−	−	+
Lactic acidosis	−	+	−	−	−
Gastrointestinal disturbance or hepatic reaction	+	++	++	++	−
Edema	−	−	+/++	−	−

+Minor clinical problem
++Major clinical problem
−Not or rarely associated with this side-effect

Other potential and demonstrated side effects related to α-glucosidase inhibitor therapy

Pneumatosis cystoides intestinalis also known as pneumatosis coli, pseudolipomatosis or intestinal emphysema is a rare condition in which gas is abnormally found in a linear or cystic form in the submucosa or subserosa of the bowel wall. Clinically, this disorder has been associated to a large variety of conditions and so its relevance must be interpreted within the clinical context. It can be suggestive of a severe underlying condition such as bowel infarction or perforation but can also be a benign incidental finding. Interestingly, since 1999, all three AGI have been associated with the typical radiographic finding. Many mechanisms have been proposed to explain the causality behind this association. It is thought to mainly involve raised intraluminal pressure due to gas production through fermentation of nonabsorbed carbohydrates. Mucosal breaks could then occur, allowing gas to dissect through tissues of the bowel wall.

Thirty case reports of pneumatosis cystoides intestinalis in patients treated with AGI have been documented [119–122]. The onset occurred from 1 week to many years after starting treatment. Patients complained of abdominal pain or distension, and/or rectal bleeding. Four patients were asymptomatic and this was an incidental finding. Conservative treatment was employed in most cases, but exploratory surgery was judged appropriate for seven patients. Treatment consists of immediate discontinuation of the drug with, in some cases, the use of antibiotics or the administration of oxygen. All thirty cases reported complete clinical and radiologic healing usually within the month following the discontinuation of the drug.

Because of gastrointestinal side effects, there has been concern about the risk of colon cancer associated with AGI. There has been no increase of colon cancer in large cohorts followed for more than 1 year [19,20,66]. Furthermore, in a large cohort study of 39 515 newly diagnosed type 2 diabetic patients of which 2918 were treated with AGI and followed for seven years, AGI treatment was associated with a lower risk of hepatic cancer (adjusted HR, 0.62; 95% CI, 0.4-0.94) [123].

A few case reports have described the association of ileus with acarbose treatment in Japanese patients [124].

In approximately 3 million patient-years of international postmarketing experience with acarbose, 62 cases of serum transaminase elevations >500 IU L^{-1} have been reported [125]. Of these 62 patients, 41 were treated with doses of 100 mg three times daily or greater. Interestingly, 33 of 45 patients for whom weight was reported weighed less than 60 kg. Therefore, the maximum recommended dose for patients <60 kg is 50 mg three times daily, increasing to 100 mg three times daily maximum for patients >60 kg. For 55 of the 59 cases where follow-up was recorded, hepatic abnormalities improved or resolved upon discontinuation. Moreover, two cases of severe hepatotoxic reaction categorized as probable idiosyncratic reaction related to acarbose have been reported [126,127]. Thus, hepatic reactions are rare and unpredictable.

The occasional observation of anemia is controversial and probably not of clinical significance. Finally, occasional reports indicate that acarbose could lower or increase digoxin plasma levels, and so monitoring should probably be done when AGI therapy is initiated or the dose is modified [128].

Overall, gastrointestinal side effects are the main clinical issue. To maximize treatment compliance, it is essential for clinicians to start patients on a low dose, titrating the dose gradually based on efficacy and tolerance, and make sure to discuss these anticipated side effects with the patients as well as their expected decrease over time.

Contraindications to α-glucosidase inhibitors

Formal contraindications to acarbose therapy are intestinal malabsorption syndromes, inflammatory bowel disease, colonic ulceration, partial intestinal obstruction, and cirrhosis. It is also contraindicated in cases of severe renal impairment (creatinine clearance <25 mL min^{-1}), in pregnant or lactating women, and in children below 12 years of age, because of a lack of data in these groups. Interestingly, however, reproduction studies have been performed in rabbits at doses up to 32 times those given to humans and have revealed no evidence of teratogenicity [125].

Since trials in diabetic cirrhotic patients have demonstrated a positive action of acarbose on glycemic control without adverse effects on liver function, restrictions related to cirrhosis could be withdrawn in the future [129]. In fact, it has been mentioned that acarbose could even be used to treat hepatic encephalopathy but there is no approved indication [130].

Indications for α-glucosidase inhibitors

Alpha-glucosidase inhibitors could be considered as monotherapy in the following cases:

1 *Patients with normal or slightly elevated fasting blood glucose and postprandial hyperglycemia*: In these patients, postprandial hyperglycemia contributes significantly to increased HbA1c [1]. This population includes most recently diagnosed patients. When diet and exercise fail to normalize blood glucose, AGI can bring glycemic control into the desirable range for an important portion of these patients.
2 *Elderly diabetic patients*: There is now evidence that this patient population significantly benefits from AGI treatment [25,30,58]. The absence of hypoglycemic risk is a major advantage in this subgroup and moderately decreased kidney function is not a contraindication.
3 *As an alternative to other oral hypoglycemic agents when they are contraindicated*: Alpha-glucosidase inhibitors can also be prescribed in combination with other hypoglycemic agents in various situations:
   ∘ *as an adjunct* to other hypoglycemic agents that have not produced adequate glycemic control. Combination of AGI

with all other treatments has demonstrated a moderate but significant, constant, and sustained glycemic improvement.

◦ *as an alternative* for patients not controlled with a combination of oral hypoglycemic agents and who refuse insulin.

The proper use of AGI requires attention on two major points:

1 To be effective, they must be administered at the onset of meals with the first bite and not later than 15 min after meals.

2 Therapy must be initiated with a low dose and titrated upward slowly based on PPG as well as gastrointestinal tolerance.

Recommended doses are as follows:

- 25–100 mg three times daily for acarbose;
  ◦ The maximum recommended dose for patients <60 kg is 50 mg three times daily
  ◦ The maximum recommended dose for patients >60 kg is 100 mg three times daily
- 25–100 mg three times daily for miglitol
- 0.2 mg three times daily for voglibose.

Conclusions

Alpha-glucosidase inhibitors are drugs that delay the digestion of complex carbohydrates by acting as competitive inhibitors of intestinal α-glucosidase enzymes that hydrolyze di-, oligo-, and polysaccharides into monosaccharides, an essential step for absorption. Thus, these drugs decrease the rise in postprandial plasma glucose and consequently insulin.

In subjects with IGT, AGI delay the onset of T2DM and hypertension, and possibly reduce macrovascular events. In type 2 diabetic patients, AGI have shown moderate but constant and sustained reductions of HbA1c (∼0.7%) regardless of concomitant antidiabetic medication.

Additional benefits of AGI are the lack of hypoglycemia with monotherapy, no weight gain, and an excellent safety profile. Gastrointestinal symptoms are the consequence of undigested carbohydrates reaching the colon, where they are fermented by bacteria, thus causing flatulence, abdominal discomfort, or bloating. Hence the necessity of initiating treatment at a low dose and increasing the dosage slowly to minimize these side effects.

[1]Diabetes Division, Department of Medicine, The University of Texas Health Science Center at San Antonio (UTHSCSA), San Antonio, TX, USA

[2]LSD Clinical Research Diabetes and Endocrinology, Merck Research Laboratories, Rahway, NJ, USA

Key points

- Type 2 diabetes mellitus (T2DM) is characterized by multiple patho-physiologic abnormalities
- Multiple antidiabetic agents used in combination will be required to correct the multiple pathophysiologic disturbances and reduce/maintain the HbA1c ≤ 6.5–7.0%
- Medications that prevent the progressive beta cell failure (GLP-1 receptor agonists and thiazolidinediones) and improve the insulin resistance (thiazolidinediones) should be considered as first line agents
- Metformin and sulfonylureas are the most commonly prescribed combination worldwide but neither drug prevents/delays beta cell failure in T2DM and neither drug improves insulin sensitivity
- Metformin and thiazolidinediones have an additive effect to reduce the HbA1c and combination therapy does not cause hypoglycemia
- Combination therapy with metformin (which increases GLP-1) plus a DPP4 inhibitor has good efficacy in reducing HbA1c and does not cause hypoglycemia
- SGLT2 inhibitors work at all stages (early to late) of the natural history of T2DM and can be used in combination with all other antidiabetic agents, including insulin
- Triple combination therapy with pioglitazone/metformin/GLP-1 receptor agonist is especially effective in normalizing the HbA1c, even in T2DM patients with a starting HbA1c > 10.0%
- Intensive insulin therapy in combination with or followed by combination therapy with metformin and/or thiazolidinedione and or SGLT2 inhibitor, and/or GLP-1 receptor agonist can be effectively employed in poorly controlled, new-onset T2DM patients to normalize HbA1c

Introduction

Type 2 diabetes mellitus (T2DM) is a complex metabolic and cardiovascular disorder with multiple pathophysiologic abnormalities. Insulin resistance in muscle and liver and β-cell failure

represent the core defects [1–3]. β-Cell failure occurs early in the natural history of T2DM and is more severe than previously thought [4–7]. In addition to the muscle, liver, and β-cell "Triumvirate", fat cells (accelerated lipolysis), GI tract (incretin deficiency/resistance), α cell (hyperglucagonemia), kidney (increased glucose reabsorption), and brain all play important roles in the development of glucose intolerance in T2DM [3]. Collectively, these eight players comprise the "Ominous Octet" (Figure 46.1) and dictate that: (i) multiple drugs in combination will be required to correct the multiple pathophysiologic defects; (ii) treatment should be based upon reversal of known pathogenic abnormalities; (iii) therapy must be started early to prevent/slow progressive β-cell failure. A treatment paradigm shift is recommended in which combination therapy is initiated with agents that correct known pathogenic defects in T2DM.

Natural history of type 2 diabetes

Individuals destined to develop T2DM inherit genes that make their tissues resistant to insulin [1–3,8–13]. Insulin resistance in liver results in overproduction of glucose during the fasting state [14] and impaired suppression of hepatic glucose production (HGP) by insulin [15], as occurs following a meal [16]. Insulin resistance in muscle [15,17–19] is manifest by impaired glucose uptake following carbohydrate ingestion, resulting in postprandial hyperglycemia [16]. Although origin of insulin resistance can be traced to its genetic background [2,8], the current diabetes epidemic is related to the obesity epidemic and physical inactivity [20]. Both obesity [21] and decreased physical activity [22] are insulin-resistant states. As long as β cells augment insulin secretion sufficiently to offset insulin resistance, glucose tolerance remains normal [1–3,23]. However, with time β cells begin to fail, and initially postprandial, and subsequently fasting plasma glucose levels
Figure 46.1 The Ominous Octet: eight distinct pathophysiologic defects contribute to the pathogenesis of type 2 diabetes mellitus. Source: DeFronzo 2009 [3].

increase, leading to overt diabetes [1–3,5–7,24]. This natural history of T2DM [1–3] is depicted in Figure 46.2 [25].

Beta-cell function

The plasma insulin response to insulin resistance typically is increased early in the natural history of T2DM (Figure 46.2). However, plasma insulin response to glucose challenge does not provide a valid index of β-cell function [26]. β-Cells respond to an increment in glucose (ΔG) with an increment in insulin (ΔI) [26]; they also increase their secretion of insulin to compensate for the insulin resistance [23,26,27]. Thus, the gold standard for β-cell function is the insulin secretion/insulin resistance (disposition) index ($\Delta I/\Delta G \div IR$). Results of the SAM Study and VAGES have shown that subjects in the upper tertile of normal glucose tolerance have lost >50% of β-cell function, while subjects in the upper tertile of IGT have lost ~80% of β-cell function [1–7]. Similar conclusions are evident from other publications [10,25,28,29]. Further, Butler et al. [30] have demonstrated that, as individuals progress from NGT to impaired fasting glucose (IFG), there is a decline in β-cell mass which continues with progression to diabetes [31].

In summary, although insulin resistance in liver and muscle are well established early in the natural history of the disease, T2DM does not occur in the absence of progressive β-cell failure.

Insulin resistance

Liver. Following an overnight fast, liver of nondiabetic individuals produces glucose at ~2 mg kg^{-1} per min [1–3,14]. In T2DM, the rate of basal HGP is increased, averaging ~2.5 mg kg^{-1} per min [1–3,14]. This amounts to addition of 25–30 g of glucose to the systemic circulation every night and is responsible for the increase in FPG concentration. This hepatic overproduction of glucose occurs despite fasting plasma insulin levels that are
Figure 46.2 Natural history of diabetes mellitus. Subjects had a euglycemic insulin clamp to measure tissue sensitivity to insulin and an oral glucose tolerance test (OGTT) to provide a measure of glucose homeostasis and β-cell function. In lean subjects with normal glucose tolerance (NGT), the mean plasma glucose and insulin concentrations during the OGTT were 115 mg dL^{-1} and 62 μU mL^{-1}, while the mean rate of insulin-stimulated glucose disposal was 265 mg m^{-2} per min. Obesity was associated with 29% decline in insulin sensitivity, but glucose tolerance remained normal because of a compensatory increase in insulin secretion. With time obese NGT individuals progress to IGT in association with a further 28% reduction in insulin sensitivity (total decrease = 57% from NGT to IGT). However, the rise in plasma glucose concentration is modest because of a further compensatory increase in insulin secretion. IGT individuals are maximally or near maximally insulin resistant, and their β cells are functioning at near maximum capacity. With time the β cells cannot continue to produce these very large amounts of insulin and the obese, as well as lean, IGT individual progress to overt diabetes in association with a marked decrease in insulin secretion without further change in insulin sensitivity. Source: DeFronzo 1988 [1] and Jallut 1990 [25].

increased two- to threefold, indicating severe hepatic resistance to insulin.

Muscle. Using the insulin clamp technique [32] with limb catheterization [1–3,15,17–19], it has conclusively demonstrated that lean, as well as obese, T2DM individuals are severely

resistant to insulin and that muscle is the primary site of insulin resistance. Multiple intramyocellular defects in insulin action are present in T2DM [1–3,33,34], including impaired glucose transport and phosphorylation [17], reduced glycogen synthesis [35], decreased glucose oxidation [5] and more proximal defects in insulin signal transduction [34,36].

Ominous Octet. In addition to the Triumvirate (β-cell failure; insulin resistance in muscle and liver) [1], at least five other pathophysiologic abnormalities contribute to glucose intolerance in T2DM [3] (Figure 46.1): (i) adipocyte resistance to antilipolytic effect of insulin leads to increased plasma FFA and elevated intracellular levels of toxic lipid metabolites in liver/muscle and β cells, causing insulin resistance and β-cell failure/apoptosis [15]; (ii) decreased incretin (GLP-1 and GIP) effect resulting from impaired GLP-1 secretion, but more importantly from severe β-cell resistance to both GLP-1 and GIP [37]; (iii) increased glucagon secretion by α cells and enhanced hepatic sensitivity to glucagon, leading to increased basal HGP and impaired HGP suppression by insulin [38,39]; (iv) enhanced renal glucose reabsorption by the SGLT2 transporter, contributing to maintenance of elevated plasma glucose levels [40]; (v) CNS resistance to the anorectic effect of insulin and altered neurosynaptic hormone secretion contributing to appetite dysregulation, weight gain, and insulin resistance in peripheral tissues and liver [41,42].

Implications for therapy

The preceding review of T2DM pathophysiology has important therapeutic implications: (i) effective treatment will require multiple drugs in combination to correct multiple pathophysiologic defects; (ii) treatment should be based upon reversal of known pathogenic abnormalities and NOT simply on reduction of A1c; (iii) therapy must be started early in the natural history of T2DM, if progressive β-cell failure is to be prevented.

Current therapeutic options as they relate to pathophysiologic derangements present in T2DM are depicted in Figure 46.3. In liver, both metformin [43–45] and thiazolidinediones (TZDs) [46–50] are potent insulin sensitizers and reduce the increased basal rate of hepatic glucose production. In muscle, TZDs are potent insulin sensitizers [46–48,51–53], whereas metformin is, at best, a weak insulin sensitizer [43,45,52]. Since TZDs work through the classic insulin signaling pathway [53,54], whereas metformin works through AMP kinase pathway [55,56], combination therapy with TZD plus metformin gives a completely additive effect to reduce HbA1c [57,60]. Further, hypoglycemia is not encountered because these drugs are insulin sensitizers. In adipose tissue, TZDs are excellent insulin sensitizers and potent inhibitors of lipolysis [61–63]. TZDs also effectively mobilize fat from muscle, liver, and β-cells, ameliorating lipotoxicity [47,62–67].

In the β cell, sulfonylureas, glinides, and incretin-based therapies (GLP-1 analogues and DPP-4 inhibitors) augment insulin secretion. However, only GLP-1 analogues [68–70] and TZDs [71,72] improve/preserve β-cell function and demonstrate durability of glycemic control [60,68,72–81]. Nonetheless, the two most commonly prescribed drugs worldwide are sulfonylureas and metformin, and neither exert any β-cell protective effect.

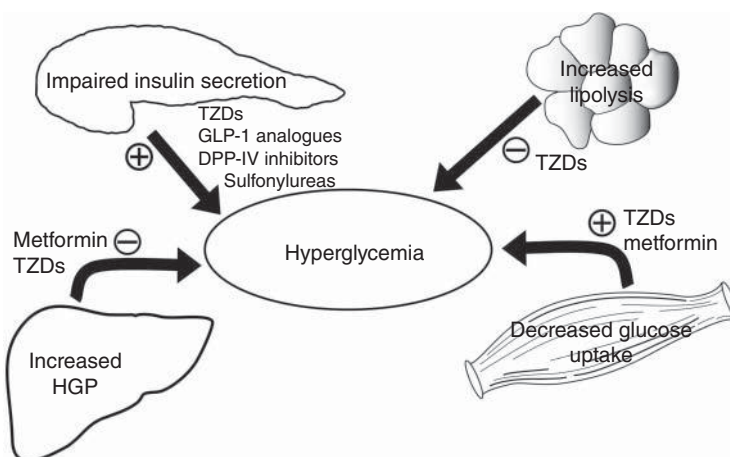
The GLP-1 analogue, exenatide, augments and preserves β-cell function for at least 3 years [68,69]. The β-cell protective effect of GLP-1 analogues has its onset within 24 h [70] and persists as long as GLP-1 therapy is continued [68,69,80]. Further, both exenatide and liraglutide inhibit the appetite center in CNS leading to weight loss [80–84], inhibit glucagon secretion [82–84], and delay gastric emptying [82–84]. By promoting weight loss and depleting lipid from muscle and liver, GLP-1 analogues also improve muscle and hepatic insulin sensitivity [68,69]. GLP-1 analogues correct multiple cardiovascular risk factors [80,85]. Although DPP-4 inhibitors share some characteristics with GLP-1 analogues, they do not raise plasma GLP-1 levels sufficiently to offset the β cell GLP-1 resistance [86,87]. Not


Figure 46.3 Therapeutic options in type 2 diabetic patients based upon their ability to reverse specific pathophysiologic abnormalities present in the disease.

surprisingly, their ability to augment insulin secretion and reduce HbA1c are significantly less than GLP-1 analogues [86,87], and they do not promote weight loss [88]. The major mechanism of action of DPP-4 inhibitors to improve glycemic control is mediated via inhibition of glucagon secretion and subsequent decline in hepatic glucose production [89,90].

The recently approved sodium glucose transporter 2 (SGLT2) inhibitors demonstrate modest efficacy in reducing HbA1c, promote weight loss, reduce blood pressure, and can be added to all approved antidiabetic agents including insulin [40,91] .

Combination therapy

In the present chapter we discuss combination therapy in two clinical situations: (i) initiation of combination therapy in newly diagnosed T2DM patients; (ii) add-on therapy in T2DM patients inadequately controlled with one or more oral agents. In the latter situation, we review use of basal insulin in T2DM patients suboptimally controlled with oral agents or GLP-1 analogues. Use of a mixed-split insulin regimen in this situation will not be addressed.

Newly diagnosed T2DM patients

When initiating combination therapy in newly diagnosed T2DM patients, the following considerations are of paramount importance:

1 Therapy should be able to achieve the desired level of glycemic control: HbA1c ≤ 6.5% (EASD and AACE) [92] and ≤7.0% (ADA) [93]. However, we believe that, in newly diagnosed T2DM patients without cardiovascular disease, optimal glycemic control should be HbA1c <6.0% and as close to normal as possible, while avoiding untoward adverse events, primarily hypoglycemia [3,94]. This is consistent with the expanded ADA statement [93].

2 In the majority of newly diagnosed T2DM patients, monotherapy will not be sufficient to reduce HbA1c <6.5–7.0%, or most optimally <6.0%. Therefore, combination therapy will be required [3].

3 The medications used in combination therapy should have an additive effect and individual drugs should correct known pathophysiologic disturbances present in T2DM. Otherwise, long-term durability of glycemic control will not be achieved.

4 Progressive β-cell failure is responsible for the progressive HbA1c rise in T2DM [1–7]. Therefore, medications used to treat T2DM should preserve/improve β-cell function to produce a durable effect on glycemic control.

5 Because underlying insulin resistance is a core defect in T2DM and accelerates β-cell failure, medications should also ameliorate insulin resistance in muscle and liver.

6 Because T2DM is a cardiovascular equivalent, it is desirable that drugs exert beneficial effects to improve cardiovascular (CV) risk factors and decrease CV events.

7 Obesity is a major problem in T2DM. Therefore, it is desirable that combination therapy be weight neutral and, ideally, promote weight loss.

8 Combination therapy should be safe.

No single antidiabetic agent can correct all of these pathophysiologic disturbances and multiple agents, used in combination, will be required to optimally control T2DM patients.

Initial combination therapy in new onset diabetes

Rationale

Although ADA/EASD recommend starting therapy with metformin as monotherapy [93], many considerations favor initiating combination therapy in newly diagnosed T2DM individuals [3]. Initiating therapy with multiple agents that have different mechanisms of action allows correction of more metabolic abnormalities than can be achieved with monotherapy. Further, the HbA1c decrease produced by a single antidiabetic agent, for example metformin, sulfonylurea, pioglitazone, GLP-1 analogue, is ~1.0–1.5% depending upon starting HbA1c.Thus, in newly diagnosed T2DM with HbA1c > 8.0–8.5%, it is unlikely that a single agent will achieve the recommended goal (HbA1c < 6.5–7.0%) and virtually no one will achieve HbA1c < 6.0%. When maximum dose metformin, sulfonylurea or thiazolidinedione is initiated as monotherapy, only 25–40% of newly diagnosed T2DM subjects achieve HbA1c < 6.5–7.0% [95,96], and an even smaller percentage achieve an acceptable HbA1c with acarbose or repaglinide [97]. Thus, most patients with HbA1c > 8.0–8.5% will require initial combination therapy. Moreover, because different agents lower plasma glucose via different mechanisms, combination therapy will have an additive or even synergistic effect to reduce HbA1c compared to each agent alone. Simultaneous improvements in β-cell dysfunction and insulin sensitivity are more likely to cause durable HbA1c reduction. Lastly, initiation of combination therapy allows use of submaximal doses of each antidiabetic agent and results in a lower adverse event rate. Consistent with this approach, AACE recommends starting newly diagnosed diabetic subjects with HbA1c > 8.0% on multiple antidiabetic agents [92]. A list of available combination tablets and their efficacy in reducing A1c is provided in Tables 46.1 and 46.2.

Sulfonylurea plus metformin

The most commonly used combination therapy worldwide is metformin plus sulfonylurea. Because the glucose-lowering mechanisms with metformin (inhibition of hepatic glucose production) and sulfonylureas (enhanced insulin secretion) differ, combined sulfonylurea/metformin therapy has an additive effect to reduce HbA1c versus either agent alone [44,95,96]. Sulfonylurea addition to metformin, metformin addition to sulfonylurea and initiation of combination metformin/sulfonylurea

Table 46.1 Available fixed-dose combination tablets

Combination	Agent	Ingredients	Dose (mg)
Metformin plus sulfonylurea			
	Glucovance	Glyburide/metformin	1.25/250, 2.5/500, 5/500
	Metaglip	Glipizide/metformin	2.5/250, 2.5/500, 5/500
Metformin plus repaglinide			
	Prandimet	Repaglinide/metformin	1/500, 2/500
Metformin plus DPP-4 inhibitors			
	Januamet	Sitagliptin/metformin	50/500, 50/1000
	Kombiglyze	Saxagliptin/metformin	5/500, 5/1000, 2.5/1000
Metformin plus thiazolidinedione			
	Actoplus Met	Pioglitazone/metformin	15/500, 15/850, 15/1000, 30/1000
	Avandamet	Rosiglitazone/metformin	2/500, 4/500, 2/1000, 4/1000
Sulfonylurea plus thiazolidinedione			
	Avandaryl	Rosiglitazone/glimepride	4/2, 4/4, 8/2, 8/4
	Duetact	Pioglitazone/glimepride	30/2, 30/4

Table 46.2 Effect of initial combination therapy on glycemic control in drug-naïve subjects

Combination	Initial HbA1c	Decrease in A1c	% with A1c <7.0%	Reference
Metformin/glyburide	8.4%	2.2	66	[95]
Metformin/nateglinide	8.3%	1.4	70	[97]
Metformin/pioglitazone	8.7%	1.83	64	[103]
Metformin/rosiglitazone	8.8%	2.3	77	[104]
Metformin/sitagliptin	8.8%	1.9	66	[106]
Metformin/vildagliptin	8.7%	1.8	65	[108]
Metformin/dapagliflozin	9.1%	1.98	53	[115]
Pioglitazone/vildagliptin	8.7%	1.9	65	[109]
Pioglitazone/sitagliptin	9.5%	2.4	60	[110]
Pioglitazone/linagliptin	8.6%	1.06	43	[111]
Pioglitazone/alogliptin	8.8%	1.71	63	[113]

therapy in drug-naïve T2DM subjects lowers HbA1c by ∼2.0%. Herman et al. [95] randomized 144 T2DM subjects to metformin alone, glyburide alone or combination therapy. The decrease in HbA1c in subjects receiving metformin alone and glyburide alone was 0.9% and 1.3%, and only 66% and 62%, respectively, achieved the treatment goal. The decrease in HbA1c in subjects started on combination therapy was 2.2%. Garber et al. [96] randomized 806 drug-naïve T2DM patients to glyburide (2.5 mg), metformin (500 mg), glyburide/metformin (1.25/250 mg), or glyburide/metformin (2.5/500 mg). Patients receiving combination glyburide/metformin therapy (both low and high doses) had significantly greater HbA1c reductions (1.48% and 1.53%, respectively) than subjects receiving metformin alone (1.03%) or glyburide alone (1.24%). Although the HbA1c decrease was comparable in both combination therapy groups, hypoglycemia was threefold more common in the high- versus low-dose combination group (16% vs. 5%). Moreover, despite greater HbA1c decrease with glyburide/metformin (1.25/250 mg) versus glyburide alone, hypoglycemic events

were slightly lower in the combination group (5.1% vs. 6.3%). These results demonstrate that initial combination therapy with metformin/sulfonylurea has an additive effect to reduce HbA1c and allows use of submaximal doses of each drug, minimizing hypoglycemia and weight gain.

Amongst sulfonylurea/metformin combination tablets, Glucovance® (metformin/glyburide) has achieved the most widespread usage. In drug-naïve T2DM patients (HbA1c = 8.2%), Glucovance reduced HbA1c by 1.5%, and this was 0.5% more than when glyburide and metformin were administered as separate tablets. The greater HbA1c decrement in Glucovance-treated patients resulted from an augmented insulin response from increased glyburide bioavailability. Consistent with this, T2DM patients on chronic treatment with glyburide and metformin as separate tablets, experienced an additional 0.6% HbA1c reduction when switched to Glucovance [99]. Metaglip™ (metformin/glipizide) is slightly less potent than Glucovance in reducing HbA1c, most likely because Metaglip formulation does not result in increased glipizide bioavailability.

A major limitation of combination therapy with sulfonylurea/metformin is that neither agent preserves β-cell function or improves insulin sensitivity in muscle. UKPDS demonstrated that, despite an additional HbA1c decrease when metformin was added to glyburide or glyburide to metformin, HbA1c progressively increased and after 10 years the majority (~60%) of subjects required insulin therapy [20,61].

Metformin plus repaglinide/nateglinide
Repaglinide and nateglinide are short-acting insulin secretagogues, given 2–3 times daily with meals. Because metformin primarily reduces FPG by suppressing HGP, while nateglinide targets postprandial hyperglycemia, combination metformin/nateglinide therapy improves both fasting and postprandial hyperglycemia. Three large clinical trials [97,98,100] have demonstrated that combined metformin/nateglinide therapy safely and effectively lowers HbA1c in drug-naïve T2DM patients. In 701 drug-naïve T2DM individuals (HbA1c ~8.3%) nateglinide (120 mg) plus metformin (500 mg) versus nateglinide alone, metformin alone, and placebo decreased HbA1c by −1.4%, −0.5%, −0.8%, and +0.5%, respectively [97]. Seventy percent of subjects who received combination therapy achieved HbA1c < 7.0% versus only 34%, 41%, and 17% who received nateglinide, metformin, and placebo, respectively. Metformin had greater efficacy in lowering FPG, while netaglinide was more effective in reducing postprandial glucose levels. There were more hypoglycemic events in subjects receiving combination therapy (26%) versus nateglinide (12%) or metformin (10%) alone. However, most of these events were mild.

Two studies [98,100] comparing long-term efficacy of initial combination therapy with metformin/nateglinide versus metformin/sulfonylurea in drug-naïve T2DM individuals reported conflicting results. In PRESERVE-Beta [98] 404 drug-naïve T2DM subjects were randomized to glyburide (10 mg)/metformin (2000 mg) or nateglinide (120 mg with meals)/metformin (2000 mg). HbA1c decrease at 104 weeks was similar in both groups (1.6% in glyburide/metformin vs. −1.4 in nateglinide/metformin), and the number of subjects maintaining HbA1c < 7.0% at 2 years was similar in both groups (39% vs. 43%). Glyburide/metformin was more effective in decreasing FPG, while nateglitide/metformin was more effective in lowering postprandial glucose. Despite the similar HbA1c decrease, hypoglycemia was more common with glyburide/metformin (17.7%) versus nateglinide/metformin (8.2%). In a 52-week study Derosa et al. [100] compared the efficacy of initial combination therapy with nateglinide/metformin versus glibenclamide/metforminin in 248 drug-naïve T2DM individuals. Unlike PRESERVE-Beta, the HbA1c decrease was greater with nateglinide/metformin (from 8.1% to 6.4%) compared to glibenclamide/metformin (1.7% vs. 10.9%).

The efficacy of repaglinide (1–4 mg per meal)/metformin versus nateglinide (120 mg with meals)/metformin was examined in a 20-week open label, parallel-group, randomized trial in 192 T2DM patients. Repaglinide/metformin produced greater

HbA1c (1.3% vs. 0.7%, $p < 0.01$) and FPG (39 versus 21 mg dL^{-1}, $p < 0.01$) reductions compared to nateglinide/metformin. Paradoxically, the change in plasma glucose, glucagon and insulin concentrations AUCs after a test meal were comparable in both groups.

In summary, initial combination therapy with metformin/nateglinide and metformin/repaglinide is effective in lowering HbA1c with a lower rate of hypoglycemia compared to metformin/sulfonylurea therapy. However, long-term durability (>2 years) of this combination has never been tested.

Metformin plus thiazolidinediones
Metformin inhibits hepatic gluconeogenesis via activation of AMP kinase [55,56], while thiazolidinediones have both direct (PPAR activation) and indirect (plasma FFA reduction, depletion of intramyocellar and intrahepatic fat, increased adiponectin) effects to improve insulin sensitivity in muscle and liver [18,43–45,47,83]. TZDs also enhance/preserve β-cell function [71]. Thus, combined metformin/thiazolidinedione therapy has an additive HbA1c lowering effect with low incidence of hypoglycemia [59,60]. Metformin also reduced the MACE endpoint of myocardial infarction, stroke, and cardiovascular death in UKPDS [29], while pioglitazone corrects multiple components of insulin resistance syndrome [46,51], reduces carotid intimal thickness [73], prevents restenosis of coronary artery stents [101], and decreases coronary atheroma volume [74]. Pioglitazone also decreased the second principal endpoint (composite of myocardial infarction, stroke, death) in PROACTIVE [102]. Rosiglitazone, unlike pioglitazone, has been associated with increased incidence of cardiovascular events [27] and withdrawn from most markets worldwide.

Multiple clinical studies have demonstrated the additive metabolic benefit of TZDs plus metformin. In 600 drug-naïve T2DM patients (HbA1c ~ 8.7%) treated with pioglitazone (30 mg/metformin 1700 mg) the HbA1c decrement was twofold greater than in subjects who received pioglitazone alone (−0.96%) or metformin alone (−0.99%) and 64% of subjects achieved HbA1c < 7.0% [103]. The HbA1c decrease was accompanied by a greater decrease in FPG in the combination group (−40 mg dL^{-1}) compared to each therapy alone. Despite greater decreases in HbA1c and FPG with combination therapy, hypoglycemia was similar to the monotherapy groups. Subjects receiving combination pioglitazone/metformin experienced improvement in cardiovascular risk factors: increased HDL cholesterol, decreased plasma triglyceride, decreased small dense LDL particle number, decreased hsCRP, and increased plasma adiponectin. However, similar changes in cardiovascular risk factors were observed in subjects treated with pioglitazone alone.

Similar results were reported by Rosenstock et al. [104] using initial combination therapy with rosiglitazone (8 mg)/metformin (2000 mg) versus metformin alone and rosiglitazone alone in 468 drug-naïve T2DM patients (HbA1c = 8.8%). After 32 weeks, the HbA1c decrease was significantly greater in

subjects receiving rosiglitazone/metformin (−2.3%) versus metformin alone (−1.81%) and rosiglitazone alone (−1.6%). Rosiglitazone/metformin did not increase risk of hypoglycemia compared to either monotherapy and produced greater decrease in hsCRP and increase in plasma adiponectin concentration, which did not differ from changes observed with rosiglitazone alone.

In summary, initial combination therapy with pioglitazone/metformin offers multiple advantages: excellent glycemic control, improved cardiovascular risk profile, regression of established coronary artery atheroma volume, decreased cardiovascular events (PROactive), correction of core T2DM pathophysiologic defects (insulin resistance and impaired β-cell function), and low incidence of hypoglycemia.

Metformin plus DPP-4 inhibitor

DPP-4 inhibitors lower HbA1c by increasing plasma GLP-1/GIP levels, leading to increased glucose-stimulated insulin secretion and inhibition of glucagon secretion [89,90]. Metformin also increases plasma GLP-1 levels [105]. Thus, the combination of metformin (reduces HGP) plus DPP-4 inhibitor (insulin secretagogue) would be expected to produce an additive effect to reduce HbA1c [106]. In 1091 drug-naïve T2DM patients combined therapy with sitagliptin (100 mg)/metformin (1000 mg and 2000 mg) was compared to sitagliptin alone. In subjects receiving sitagliptin monotherapy, HbA1c decreased by −0.66% versus −0.82% in subjects receiving 1000 mg day^{-1} metformin. However, the HbA1c decrease in subjects receiving sitagliptin/metformin 1000 mg day^{-1} was −1.4% and sitagliptin/metformin 2000 mg was −1.9 versus 0.17% increase in placebo group (Figure 46.4). Both metformin doses were more effective than sitagliptin in lowering FPG. Combination of sitagliptin with either metformin dose produced additive decreases in FPG, 2h-PG, and glucose AUC versus either therapy alone (Figure 46.4). The rate of hypoglycemia was low (<2.5%) in

Figure 46.4 Efficacy of sitagliptin (S) (100 mg day^{-1}) plus metformin (M) (1000 and 2000 mg day^{-1}) versus placebo in drug-naïve type 2 diabetic patients. Source: Mannucci 2001 [105].

both combination therapy groups and did not differ from that of either therapy alone. During a 102-week extension period, subjects who received initial sitagliptin/metformin therapy continued to experience greater HbA1c reduction versus either monotherapy. However, the magnitude of HbA1c decrease began to wane at week 24, and statistical testing on durability of HbA1c control was not performed in the extension study because of high dropout; only ∼70% of subjects with HbA1c < 7.0% at week 24 maintained this target at week 102, indicating progressive loss of efficacy [107]. This observation suggests that DPP-4 inhibitors do not alter the progressive β-cell failure that is in T2DM.

Initial vildagliptin/metformin combination therapy in drug-naïve T2DM subjects (HbA1c ∼ 8.7%) reduced HbA1c by 1.8, 1.6, 1.1, and 1.4%, respectively, in subjects receiving sitagliptin/metformin (2000 mg), sitagliptin/metformin (1000 mg), sitagliptin alone, and metformin alone (p <0.01 combination vs. monotherapy) [108]; 65% of subjects receiving combination therapy achieved HbA1c <7.0%. Combination therapy produced a greater FPG reduction without increased hypoglycemic risk versus monotherapy.

In summary, combination DPP-4 inhibitor/metformin therapy produces an additive HbA1c reduction compared to each monotherapy. The magnitude of HbA1c decrease is smaller than produced by combined sulfonylurea/metformin therapy. However, unlike combined sulfonylurea/metformin therapy, DPP-4 inhibitor/metformin treatment is not associated with increased hypoglycemic risk. Available 2-year data indicate that HbA1c lowering of DPP-4 inhibitor/metformin is similar to sulfonylurea/metformin.

Thiazolidinedione plus DPP-4 inhibitor

Four studies with different DPP-4 inhibitors (sitagliptin, vildagliptin, alogliptin, linagliptin) plus pioglitazone have demonstrated that combination therapy produces greater HbA1c reduction versus either agent alone in drug-naïve T2DM subjects. Initial combination therapy with vildagliptin 100 mg plus two doses of pioglitazone (15 and 30 mg) in 607 drug-naïve T2DM individuals (HbA1c ∼ 8.7%) reduced HbA1c by 1.7% (Vilda/Pio 15 mg), 1.9% (Vilda/Pio 30 mg), 1.1% (Vilda) and 1.4% (Pio) [109]. More subjects receiving vildagliptin/pioglitazone 30 mg achieved HbA1c < 7.0% (65%) versus vildagliptin alone (42%) or pioglitazone 30 mg alone (43%). Pioglitazone monotherapy was more effective than vildagliptin in lowering FPG, while vildagliptin had greater effect on postprandial glucose. Combined pioglitazone 30 mg/vildagliptin produced greater reductions in fasting and postprandial glucose versus either therapy alone. During meal tolerance test, vildagliptin alone and vildagliptin/pioglitazone produced greater increase in the ratio of plasma insulin AUC/plasma glucose AUC than pioglitazone alone. Although these results demonstrate improved β-cell function by vildagliptin, they do not exclude a beneficial effect of pioglitazone on β-cell function, since change in insulin secretion was
not factored by the severity of insulin resistance (IR). Since pioglitazone is a powerful insulin sensitizer [82,83], the effect of combined pioglitazone/vildagliptin therapy on β-cell function ($\Delta I/\Delta G \div IR$) is much greater than the ratio between the plasma insulin AUC/plasma glucose AUC. Weight gain was more common with pioglitazone versus vildagliptin monotherapy and more common with high-dose pioglitazone versus low-dose pioglitazone combination therapy. Despite greater weight gain with both pioglitazone combinations, the TZD caused a greater HbA1c decrement. Incidence of hypoglycemia was low (<1%) in combined pioglitazone/vildagliptin groups and did not differ from that in each monotherapy group.

A similar additive HbA1c lowering effect was reported in initial combination therapy with sitagliptin 100 mg/pioglitazone 30 mg compared to pioglitazone alone (−2.4% vs. −1.5%) over 54 weeks [110]. The greater HbA1c decrease with sitagliptin/pioglitazone reported by Yoon et al. [110] versus Rosenstock et al. [109] with vildagliptin/pioglitazone is explained by the higher starting HbA1c in the former study (9.5% vs. 8.7%).

Combined linagliptin/pioglitazone therapy in drug-naïve T2DM individuals reduced HbA1c by −1.06% versus −0.50% in the pioglitazone-treated group [111]. The initial HbA1c in this study was comparable to that in the Rosenstock study (8.6 vs. 8.7%) and cannot account for the smaller HbA1c decrease with combined linagliptin/pioglitazone, but could be explained by the higher Asian population (30%) in the Yoon study [110]. Increased efficacy of incretin-based therapy (DPP-4 inhibitors and GLP-1 analogues) has been reported in Asians versus other ethnic groups [112].

Combined alogliptin/pioglitazone therapy also produced an additive effect to reduce HbA1c in 655 drug-naïve T2DM patients (HbA1c ∼ 8.8%) randomized to receive 30 mg pioglitazone, 25 mg alogliptin, 12.5 mg alogliptin plus 30 mg pioglitazone, or 25 mg alogliptin plus 30 mg pioglitazone [113]. The HbA1c decrease was −1.15% (Pio), −0.96% (Alo), −1.56% (Pio + Alo 12.5 mg) and −1.71% (Pio + Alo 25 mg). The FPG decrease followed the same pattern as HbA1c and was greater in combination therapy groups versus monotherapy groups. Hypoglycemia incidence was low (<3%) and similar in all four groups.

In summary, combination therapy with DPP-4 inhibitor/pioglitazone produces an additive effect on HbA1c versus each therapy alone without increased hypoglycemic risk. Although neither pioglitazone nor DPP-4 inhibitors are recommended by ADA/EASD as initial therapy in T2DM, subjects who cannot take metformin (gastrointestinal side effects or impaired renal function) can be treated with this combination.

Combination of SGLT2 inhibitors plus metformin

Inhibitors of renal sodium glucose transporter 2 (SGLT2 inhibitors) are a novel class of antidiabetic agents recently approved in Europe and the US. Because of their unique mechanism of action to inhibit reabsorption of filtered glucose [40,91], they are equally effective in individuals with severe insulin resistance and/or severe β-cell failure, as well as in newly diagnosed T2DM [114]. Combination therapy with dapagliflozin (5 and 10 mg) plus metformin 2000 mg produced additive decreases in HbA1c with both doses compared to each monotherapy [115]. Dapagliflozin 5 mg/metformin decreased HbA1c by −2.05% from baseline HbA1c = 9.21% compared to decreases of −1.19% and −1.30% with dapagliflozin alone or metformin alone. Similar results were observed with dapagliflozin 10 mg plus metformin 2000 mg. The HbA1c decrease with dapagliflozin 10 mg was similar to that with dapagliflozin 5 mg, indicating dapagliflozin 5 mg produced a maximal reduction in HbA1c. The FPG decrease with combination dapagliflozin/metformin therapy was additive compared to each therapy alone. Approximately half of subjects receiving combination therapy with both doses of dapagliflozin/metformin reached HbA1c < 7.0% versus 35% and 25–30% with metformin and dapagliflozin monotherapy. Incidence of hypoglycemia was low (<3.0%) and similar in combination and monotherapy groups. Subjects in both combination therapy groups experienced ∼3% decrease in body weight over 24 weeks. Adverse events included small increases in urinary tract infection (∼5%), vulvovaginitis (∼10%), and balanitis (∼15%) in subjects receiving dapagliflozin.

Initial triple combination therapy

Initial triple combination therapy with sulfonylurea/metformin/pioglitazone was examined in 58 newly diagnosed T2DM patients [116]. All subjects received lead-in treatment for 3 months with metformin plus insulin. At 3 months, subjects were randomized to triple oral therapy with pioglitazone/metformin/glyburide ($n=29$) or continued with metformin/insulin ($n=29$). After the 3-month lead-in period, HbA1c decreased from 10.8% to 5.9% and during 3 years of follow-up subjects in both groups maintained the initial HbA1c reduction (6.1% and 6.0%, respectively). Although demonstrating maintenance of excellent glycemic control for 3 years with metformin/insulin or metformin/sulfonylurea/pioglitazone, the insulin dose had to be increased from 64 to 80 units per day at study end, indicating that β-cell failure continued in this group. Moreover, good glycemic control was achieved at the expense of a relatively high rate of hypoglycemia and weight gain. Insulin-treated subjects experienced 8.1 hypoglycemic events per year versus 6.1 events per year in the triple therapy group, and 55/58 study participants experienced at least one hypoglycemic event. Weight gain was greater (10.1 kg) in the triple therapy group versus the insulin/metformin group (3.3 kg).

In an ongoing study we compared initial triple therapy with pioglitazone/metformin/exenatide twice daily with the "standard" ADA approach of metformin, then add sulfonylurea, then add basal insulin in 147 newly diagnosed T2DM patients with HbA1c = 8.6% [117]. After 2 years HbA1c reduction was greater with triple therapy versus the sequential ADA approach (2.5% vs. 2.0%, $p < 0.01$), triple therapy subjects lost 1.2 kg versus weight gain of 3.6 kg with the ADA approach, and hypoglycemia

incidence was 13.6-fold higher in the ADA-treated group. These results indicate that a combination approach focused on reversing underlying insulin resistance and β-cell dysfunction is superior and safer than an intervention of sequential therapy with metformin → sulfonylurea → insulin that does not reverse underlying pathophysiologic defects in T2DM.

Combination therapy in T2DM patients inadequately controlled on antidiabetic therapy

Introduction

In this section we consider add-on combination options for T2DM patients suboptimally controlled on single or multiple oral agents. Definition of suboptimal control will vary based upon associated medical disorders, especially cardiovascular disease (CVD), patient's age, and diabetes duration. In elderly T2DM patients with long diabetes duration and clinically significant CVD, it would be prudent to choose a higher HbA1c goal, 7.0–7.5%, and avoid overly aggressive therapies that might induce hypoglycemia [118–121]. Three large prospective studies failed to demonstrate benefit of intensive glycemic control in this population. In contrast, younger patients with shorter disease duration and without CVD can benefit from more intensive glycemic control: A1c <7.0% (ADA), <6.5% (EASD), 5.5–6.0% (optimal).

Because metformin is the recommended drug of choice for initiation of therapy in most guidelines [92,122], we will focus on add-on therapy to metformin. However, in agreement with AACE [92], other agents (pioglitazone, GLP-1 analogues, and to a lesser extent DPP-4 inhibitors) are equally as effective as metformin in reducing A1c and have a more durable action because they improve β-cell function. Therefore, we also will discuss these alternative options.

Lastly, many T2DM individuals experience loss of β-cell function despite multiple oral antidiabetic agents and require addition of basal insulin to achieve glycemic control. However, our personal belief, based upon extensive clinical experience, is that long-acting insulin should not be added unless the subject has failed on a GLP-1 receptor agonist. Insulin therapy is associated with weight gain and hypoglycemia, requires dose titration, timing with meals, and frequent glucose monitoring, and is patient unfriendly. In contrast, GLP-1 analogues do not cause hypoglycemia, promote weight loss, do not require dose titration or intensive glucose monitoring, and are more patient friendly.

Sulfonylureas/glinides: the "treat-to-fail" approach

Until recently, sulfonylureas have been considered the preferred drug of choice for add-on therapy to metformin in suboptimally controlled T2DM patients. This is attributed to their low cost and rapid onset of hypoglycemic effect. However, they lack
Figure 46.5 Effect of metformin monotherapy, sulfonylurea monotherapy, and convention therapy (weight loss/exercise) in newly diagnosed type 2 diabetic patients in the UKPDS. Source: UK Prospective Diabetes Study (UKPDS) Group 1998 [91]. Reproduced with permission of Elsevier.

"glycemic durability" and, within 1–2 years of treatment initiation, they lose their efficacy, resulting in a steady HbA1c rise to or above pretreatment levels [72] (Figure 46.5). Long-term studies examining durability of glycemic control with glinides are not available. However, nateglinide failed to prevent patients with impaired glucose tolerance from progressing to overt T2DM [123]. In a 2-year study in newly diagnosed T2DM subjects, durability of netaglinide plus metformin was comparable to glyburide plus metformin [123] and both groups experienced progressive HbA1c rise after the first year. Since deterioration of glycemic control is largely accounted for by a progressive decline in β-cell function [3,30], it is clear that both sulfonylureas and glinides fail to prevent the progressive β-cell failure [3,30] that is characteristic of T2DM. Consistent with this, *in vitro* studies have demonstrated a pro-apoptotic β-cell effect of sulfonylureas and glinides [124–128].

UKPDS clearly demonstrated that sulfonylureas had no β-cell protective effect in newly diagnosed T2DM patients [129]. After an initial drop in HbA1c, sulfonylurea-treated patients experienced progressive deterioration in glycemic control that paralleled the HbA1c rise in conventionally treated patients (Figure 46.5). In UKPDS sulfonylureas had no significant protective effect against atherosclerotic cardiovascular complications [24] and some studies have suggested that sulfonylureas may even accelerate atherogenesis [130,131]. Metformin-treated patients in UKPDS, after an initial decline in A1c, also experienced progressive deterioration in glycemic control (Figure 46.5) [132]. Using HOMA-β, UKPDS demonstrated that the relentless HbA1c rise observed with sulfonylureas and metformin resulted from progressive β-cell failure and within 3–5 years ~50% of diabetic patients required an additional pharmacologic agent to maintain HbA1c <7.0% [133–138]. Although some *in vitro* evidence suggests metformin may improve β-cell function [139], *in vivo* data from UKPDS fail to support a role for metformin in preservation of

β-cell function in humans. Importantly, however, metformin reduced macrovascular events in UKPDS [132], although by today's standards the number of diabetic subjects in the metformin arm ($n = 342$) would be inadequate to justify any conclusions about cardiovascular protection.

UKPDS was designed as a monotherapy study. After 3–5 years, it became evident that neither metformin nor sulfonylurea monotherapy could prevent progressive β-cell failure and stabilize HbA1c at its starting level (133–137). Therefore, the study protocol was altered to allow metformin addition to the sulfonylurea arm and sulfonylurea addition to metformin [133–137]. Although addition of the second agent temporarily improved glycemic control, progressive β-cell failure continued and HbA1c rose progressively.

Multiple long-term (>1.5 years), active-comparator or placebo-controlled studies have examined the ability of sulfonylureas to produce durable HbA1c reduction in T2DM. Each study [60,73,75,123,129,140–143] showed that, after an initial decline in HbA1c, a variety of sulfonylureas (glyburide, glimepiride, and gliclazide) were associated with progressive β-cell failure with loss of glycemic control (Figure 46.6). There are no exceptions to this consistent loss of glycemic control with sulfonylureas after the initial 18 months of therapy. Thus, *evidence-based medicine* documents that the glucose-lowering effect of sulfonylureas is not durable and is associated with progressive β-cell failure [60,73,75,123,129,133–137,140–144].

Sulfonylurea treatment is associated with significant weight gain [145] and hypoglycemia [19,129]. No study has clearly implicated sulfonylureas/glinides as having a negative effect on cardiovascular events [146,147]. However, glibenclamide (glyburide) impairs ischemic preconditioning [49,148], and a possible association between sulfonylureas and adverse cardiovascular outcomes has been suggested [149–152]. However, other studies with gliclazide and nateglinide failed to find such

an association [120,123,153–155]. Amongst β-cell secretagogues, shorter acting glinides and gliclazide are associated with reduced hypoglycemia compared to longer acting sulfonylureas such as glibenclamide [156–158].

In conclusion, we believe that sulfonylureas and glinides represent a poor option as add-on therapy to metformin, because they are associated with weight gain, hypoglycemia, progressive β-cell failure, and deterioration of glycemic control. The rapid, but short-lived, hypoglycemic effect is the primary advantage of this class and sulfonylureas can be used to initiate a short course of intensive glycemic control before instituting a more durable treatment plan. It should be recognized, however, that in many countries other newer antidiabetic agents (pioglitazone, GLP-1 analogues, DPP-4 inhibitors) are not available and/or are very expensive. In such circumstances, sulfonylureas may be the only option.

Pioglitazone: unique benefits, unique side effects

Rosiglitazone has been removed from the worldwide market because of cardiovascular safety concerns [159], and pioglitazone is the only representative of the TZD class. Pioglitazone is unique in that it exerts both a β-cell protective effect (71) and is a powerful insulin sensitizer in muscle and liver [46,51,160]. Not surprisingly, it has a durable effect of reducing HbA1c [123,141,161] with low risk of hypoglycemia [162].

Eight long-term (>1.5 years) active comparator or double-blind, placebo-controlled studies with TZDs (Figure 46.7) [60,73–75,123,141–143] have demonstrated that, after an initial decline in A1c, durable glycemic control is maintained because of preserved β-cell function in T2DM. In addition, there are six studies which demonstrate that TZDs prevent progression of IGT to T2DM [163–168]. These studies demonstrate that, in addition to their insulin sensitizing effect, TZDs had a major action to preserve β-cell function. In ACT NOW,
Figure 46.6 Long-term (≥1.5 years) studies examining the effect of sulfonylurea therapy on A1c. See text for a more detailed discussion. Source: DeFronzo 2009 [3].
Figure 46.7 Long-term (≥1.5 years) studies examining the effect of thiazolidinediones on A1c. See text for a more detailed discussion. Source: DeFronzo 2009 [3].

marked improvement in insulin secretion/insulin resistance (disposition) index (gold standard measure of β-cell function) was demonstrated with OGTT and FSIVGTT [168]. Similar results have been demonstrated in TRIPOD (troglitazone) and PIPOD (pioglitazone) [164,167]. Many *in vivo* and *in vitro* studies with human/rodent islets have shown that TZDs augment/preserve β-cell function [169–173].

Pioglitazone has additional beneficial pleiotropic properties: increases HDL cholesterol [51,174], reduces plasma triglycerides [51,175], decreases blood pressure, improves endothelial dysfunction, ameliorates NASH [176,177], and reduces inflammation [51,178–181]. Pioglitazone also reduced cardiovascular events in PROactive and phase 3 trials in the United States [102,182], slowed progression of carotid IMT [73,183], and reduced coronary atheroma volume [163].

Physicians must be cognizant of side effects associated with pioglitazone. Pioglitazone causes fat weight gain [60], but the greater the weight gain, the greater is the A1c decline, and the greater are the improvements in insulin sensitivity and β-cell function [47,71]. Pioglitazone also enhances salt and water retention and can exacerbate underlying diastolic dysfunction, leading to CHF [184–190]. Diuretics that work in the collecting duct (spironolactone, aldoctone, triamterine) effectively promote dieresis when fluid retentions occurs with pioglitazone therapy. A small increase in bone fractures, primarily related to trauma, has been documented in postmenopausal females [191], but not in premenopausal females or males and can be avoided by not using pioglitazone in this population, especially if bone mineral content is decreased. Although a slight increase in bladder cancer [192,193] has been reported in some studies, 8-year follow-up of a large prospective FDA-mandated study demonstrated a hazard ratio of 0.98 in pioglitazone versus non-pioglitazone-treated diabetics [194]. Lastly, a starting pioglitazone dose of 15 mg day^{-1} titrated to 30 mg day^{-1},

provides 70–80% of glycemic efficacy with minimal side effects. Titrating to 45 mg day^{-1} provides only a modest further increase in efficacy and a marked increase in side effects.

Pioglitazone/metformin combination therapy offers an effective, durable therapy that retards β-cell failure with little hypoglycemic risk. In a 24-week trial, pioglitazone/metformin reduced A1c by 1.8% (baseline A1c 8.6%), which was greater than the 1.0% reduction observed with metformin alone or pioglitazone alone [195]. As add-on to failing metformin therapy, pioglitazone reduced A1c by 0.9% over 2 years [60]. This combination has added value by improving disease parameters associated with NASH or NAFLD [66,176,177,196–199].

Combining pioglitazone with insulin effectively reduces A1c, but may cause excessive fluid retention and CHF [187]. Combining pioglitazone with SGLT-2 inhibitor may reduce peripheral edema [200] due to the diuretic effect of the SGLT2 inhibitor. Combining pioglitazone with GLP-1 analogue offsets the fat weight gain associated with pioglitazone monotherapy [201], and we particularly like this combination with or without metformin to institute therapy in newly diagnosed T2DM patients [3] (see subsequent discussion).

Glucagon-like peptide-1 analogues: robust glycemic control and weight loss

GLP-1 analogues offer a compelling option as add-on therapy to metformin due to their unique mode of action, their efficacy, promotion of weight loss [79,202–206], and low hypoglycemic risk [201,204,205,207]. Most importantly, studies have demonstrated durable glycemic control and β-cell preservation with exenatide for up to 3 years [69,80,208–211]. GLP-1 analogues have unique ability to restore β-cell glucose sensitivity [68] by augmenting glucose transport, activating glucokinase [212,213], increasing Pdx [214–217], and replenishing β-cell insulin stores [218]. Because GLP-1 levels achieved with GLP-1 receptor analogues are in pharmacologic range (~80–90 pM), they overcome β-cell incretin resistance and markedly augment insulin secretion. Increased insulin and reduced glucagon secretion [87] inhibit basal hepatic glucose production (reduce FPG) and enhance HGP suppression following a meal (improved postprandial hyperglycemia). GLP-1 analogues do not have a direct insulin sensitizing effect, but they augment insulin sensitivity secondary to weight loss. Combined pioglitazone/exenatide therapy reduces hepatic fat content and markers of liver damage in T2DM [199]. The primary side effect of GLP-1 analogues is nausea, which occurs in ~25% of individuals and ~5% cannot tolerate them because of severe nausea or vomiting [79,219,220].

As a comprehensive treatment plan, GLP-1 receptor agonists, in combination with metformin plus pioglitazone, comprise an effective triple therapy combination targeting glycemic control and pathophysiologic processes which comprise the Ominous Octet [3] (Figure 46.8).
Figure 46.8 Pathophysiologic disturbances reversed by triple combination therapy in type 2 diabetic patients treated with metformin plus pioglitazone plus a GLP-1 analogue.

Metformin + GLP-1 analogue + pioglitazone: the pathophysiologic option

Combination therapy with a biguanide, thiazolidinedione, and GLP-1 analogue offers a rational therapeutic approach targeting multiple pathophysiologic abnormalities in T2DM: muscle insulin resistance (pioglitazone), adipocyte insulin resistance (pioglitazone), pancreatic β-cell failure (GLP-1 analogue and pioglitazone), hepatic insulin resistance (metformin and pioglitazone), and excessive glucagon secretion (GLP-1 analogue) [3] with the added advantage of weight loss (GLP1 analogue) [209]. In a 20-week study of 73 T2DM patients treated with rosiglitazone, exenatide, or both (as add-on to metformin), significant improvements in β-cell function and insulin sensitivity were noted, with weight loss in all exenatide-treated groups [209]. In 233 T2DM patients treated with a thiazolidinedione plus metformin addition of exenatide reduced HbA1c by 1.0% and body weight by 1.5 kg [201]. Similar results have been reported by Liutkus et al. [221] and liraglutide addition to T2DM patients suboptimally controlled on metformin/rosiglitazone reduced HbA1c by 1.5% [222]. Newer once-weekly GLP-1 preparations provide all of the physiologic benefits of exenatide and liraglutide and facilitate patient adherence [223]. In poorly controlled T2DM patients, Bydureon® addition to metformin decreased A1c by 1.5% and caused 2.3 kg weight loss [205].

Metformin + basal insulin: reliable but old fashioned

Multiple studies have demonstrated that addition of basal insulin, glargine [224–229], and detemir [230,231] to metformin reduces A1c by 1.1–1.7%. However, this combination is associated with weight gain and hypoglycemia and does not correct any pathophysiologic abnormality present in T2DM

[227,229–231]. It also introduces the need for self blood glucose monitoring to optimally control glycemia [232,233].

Metformin + exenatide + basal insulin: the complementary combination

The rationale for this combination is based upon the complementary effects of exenatide to reduce postprandial glucose and basal insulin to reduce FPG. Reduction in postprandial glucose results from exenatide's effect to delay gastric emptying and inhibit HGP secondary to stimulation of insulin and inhibition of glucagon secretion [234]. The primary effect of basal insulin is to inhibit HGP during sleeping hours, leading to a reduction in FPG [228,235,236].

Combination therapy of basal insulin with exenatide or liraglutide has been approved in the US. In poorly controlled T2DM patients on insulin plus oral agents, exenatide reduced HbA1c (−0.87%), body weight (−5.2 kg), premeal and basal insulin dose, and sulfonylurea use [219]. In a short-term study, exenatide addition to insulin glargine plus metformin significantly reduced postprandial glucose excursion and HbA1c [237]. In a 30-week prospective study, addition of twice-daily exenatide to basal insulin reduced HbA1c by −0.69% and weight by −2.7 kg without increased hypoglycemia [238]. Combined liraglutide/insulin therapy in poorly controlled T2DM patients on metformin decreased HbA1c by 0.5%, primarily from a decrease in FPG [239]. In a survey based on data from the ABCD database, combination insulin/exenatide therapy effectively reduced A1c but was associated with a slightly higher rate of hypoglycemia (8.9 vs. 6.1%, $p < 0.001$) [240]. Improved glycemic control and weight loss have been reported in a 24-month retrospective analysis of poorly controlled T2DM patients following initiation of exenatide/glargine [241] and in a retrospective review of national US insurance claims database [242].

DPP-4 inhibitors: weak but easy

Dipeptidyl peptidase-4 inhibitors (DPP-4i) have gained widespread use as add-on therapy to metformin [243] because of weight neutrality, modest efficacy, and safety [244–249]. DPP-4i have a weak effect to augment insulin secretion [87,90,250]; their major effect to improve glycemic control is related to inhibition of glucagon secretion and resultant suppression of HGP [90]. In T2DM metformin increases endogenous GLP-1 secretion [105,251,252]. Combined metformin/DPP-4i therapy increases GLP-1 levels [253] and has an additive, even synergistic glucose lowering effect [247,254]. Compared with GLP-1 analogues, DPP-4i are clearly less effective. In a head-to-head cross-over study, exenatide was markedly superior to DPP-4i in reducing postprandial glucose, augmenting insulin and inhibiting glucagon secretion, and promoting weight loss [87]. In a head-to-head study, liraglutide reduced A1c by 0.6% more than sitagliptin [255]. Other studies have demonstrated superior efficacy of GLP-1 analogues in reducing A1c [256,257], augmenting β-cell function [258], and promoting weight loss [259]. A major advantage of DPP-4i is their ease of administration and excellent safety profile.

In combination with sulfonylureas, increased hypoglycemia has been observed with DPP-4i [244,260]. Because sulfonylureas have no effect to preserve β-cell function and cause hypoglycemia when used with DPP-4i, this combination is not recommended. In triple combination with metformin/pioglitazone (30 mg), the DPP-4i alogliptin resulted in better glycemic control and fewer pioglitazone dose-dependent side effects (edema and anemia) compared to metformin plus a higher dose of pioglitazone (45 mg) [261]. This study, as well as triple combination studies with metformin/ pioglitazone/GLP-1 analogue [222,262], present a compelling new approach to diabetes therapy, similar to the hypertension treatment paradigm in which submaximal doses of therapeutic combinations result in safer, more robust effects.

DPP-4i plus metformin provide an attractive option for the geriatric diabetic population which is at increased risk of drug-related side effects, especially hypoglycemia. All published studies with DPP-4i have shown them to be as, if not more, effective in reducing A1c in elderly versus younger T2DM patients with an excellent safety profile [263–266]. DPP-4 inhibitors also appear to be especially effective in Asian populations.

Basal insulin analogues: when the β cells fail …

Insulin is the most potent antihyperglycemic available and, in theory, should be able to achieve normoglycemia in all T2DM patients [267,268]. Insulin is the only drug that can control glycemia when β cells have failed and patients no longer respond to oral agents/GLP-1 analogues [269]. However, insulin therapy is associated with weight gain and hypoglycemia. In ACCORD [119] diabetic patients gained 3 kg over 3 years, and in the study by Henry et al. [270] T2DM patients gained 8.7 kg over 6 months. Weight gain results from reduction in

glucosuria [271] and appetite stimulation with increased food intake. The least weight gain is observed with long-acting basal analogues (glargine and detemir) compared to short-acting insulins and NPH [230,271–274]. Weight gain associated with insulin therapy can aggravate insulin resistance, necessitating an increase in insulin dose to maintain glycemic control.

Hypoglycemia is another obstacle with insulin therapy [119]. Addition of basal insulin to poorly controlled T2DM patients increases the incidence of hypoglycemia to ~4–5 events per patient year [229,272]. If premeal rapid-acting insulin must be added to achieve glycemic control, the incidence of hypoglycemia and weight gain increases markedly [275]. Thus, in ACCORD [119] insulin therapy was associated with an annualized hypoglycemic rate requiring medical assistance of 3.1% and in the Henry study the incidence of hypoglycemia was even greater, 4.1 events per month per patient in the first month, decreasing to 1.3 events per month by 6 months [270].

There has been renewed interest in use of intensive insulin therapy to "preserve β-cell function." In a large Swedish trial, newly diagnosed T2DM patients received premixed 30/70 insulin or glibenclamide. After 1 year, glucagon-stimulated C-peptide was significantly increased in the insulin-treated, but not glibenclamide group despite similar HbA1c reduction. After two years, HbA1c increased in the glibenclamide group and remained unchanged in the insulin group [276]. Similar results were observed in a 6-month study with basal insulin in newly diagnosed T2DM patients and improved glycemic control was attributed to enhanced β-cell function [277]. Even short courses of intensive insulin therapy can cause prolonged improvement in β-cell function in newly diagnosed T2DM patients [278]. The beneficial effect of intensive insulin therapy on β-cell function results from correction of lipotoxicity [279] and/or glucotoxicity [280].

When comparing add-on insulin to other therapeutic options, our personal belief, based upon extensive clinical experience, is that a long-acting insulin should not be added unless the subject has had a trial with a GLP-1 receptor agonist and failed.

Triple combination therapy with long-acting insulin, GLP-1 analogue, and metformin in patients with partial response to GLP-1 analogue plus metformin is very effective in achieving normoglycemia, reducing insulin dose, preventing weight gain, and reducing hypoglycemic risk [237,238,240–242].

Conclusion and recommendations

Treating diabetic patients requires in-depth knowledge of the benefits and risks of the multiple therapeutic agents, their mechanisms of action, and the patient's needs, lifestyle, and associated medical disorders. Emphasis should be placed on medications that ameliorate insulin resistance and prevent progressive β-cell failure to achieve a durable reduction in HbA1c. T2DM is a multifactorial disease and antidiabetic medications must reverse the basic underlying pathophysiologic disturbances rather than solely reduce blood glucose

[3]. We advocate a therapeutic approach based not only the drug's glucose lowering efficacy and durability, but also on its effect on weight, blood pressure, lipid profile, cardiovascular protection, side-effect profile, and method of delivery [281]. Most importantly, we strongly recommend medications that reverse underlying pathophysiologic disturbances [1–3].

Metformin is recommended by EASD/ADA/AACE as initial therapy in newly diagnosed T2DM individuals. It reduces the elevated rate of basal HGP, may reduce cardiovascular risk, and does not cause hypoglycemia. However, it lacks effect on the β cell and its effect on HbA1c is not durable [72,133–137,282]. In newly diagnosed T2DM subjects with HbA1c >8.0%, metformin monotherapy will not achieve adequate glycemic control and combination therapy should be initiated, preferably with pioglitazone $(15–30\,mg\,day^{-1}) \pm$ GLP-1 analogue or DPP-4i. All of these options will achieve the desired glycemic goal (HbA1c <6.5–7.0%) in most (70–80%) patients. Only TZDs [161] and GLP-1 analogues [211] have been shown to produce durable HbA1c reduction. Moreover, pioglitazone (PROactive and US phase 3 studies) has proven cardiovascular efficacy and does not cause hypoglycemia [102,181].

If initial combination therapy with metformin plus pioglitazone or addition of pioglitazone to metformin-failing subjects fails to achieve the desired HbA1c goal, we recommend addition of a GLP-1 analogue. GLP-1 analogues effectively lower HbA1c without hypoglycemia, promote weight loss, and improve many cardiovascular risk factors. DPP-4 inhibitors are less effective than GLP-1 analogues in reducing HbA1c and do not promote weight loss but have an excellent safety profile. We do not advocate add-on therapy with sulfonylureas or insulin because they promote weight gain and cause hypoglycemia. Moreover, UKPDS and multiple other studies have demonstrated that sulfonylureas are associated with progressive β-cell failure and loss of glycemic control.

In summary, sequential therapy with metformin, addition of sulfonylurea with subsequent addition of insulin represents the "treat to fail" algorithm. In contrast, initial combination therapy with metformin, pioglitazone, and/or GLP-1 receptor agonist provides a more rational physiologic approach and represents the approach "most likely to succeed."

CHAPTER 47

New drugs for the treatment of diabetes mellitus

Clifford J. Bailey

School of Life and Health Sciences, Aston University, Birmingham, UK

Key points

- The heterogeneous and progressive nature of type 2 diabetes requires a variety of therapeutic options to control blood glucose.
- Longer-acting glucagon-like peptide-1 (GLP-1) receptor agonists and hybrid peptides that combine the properties of GLP-1 with other glucoregulatory peptides are being developed.
- New dipeptidyl peptidase-4 (DPP-4) inhibitors, glucokinase activators and agonists for fatty acid receptors such as GPR40 have been shown to improve endocrine functions of the pancreatic islets.
- Proof of principle has been established for nonpeptide GLP-1 receptor agonists, insulin mimetics, and sirtuin activators.
- Novel approaches to potentiate insulin action include phosphatase inhibitors and compounds that increase insulin receptor and early postreceptor signaling.
- Various adipokines and fibroblast growth factor 21 have been identified as possible targets or templates for development of new glucose-lowering therapies.
- Selective peroxisome proliferator-activated receptor (PPAR) modulators, glucagon receptor antagonists and cellular glucocorticoid inhibitors have shown potential.
- Agents that alter cellular energy metabolism (e.g. adenosine monophosphate-activated protein kinase activators) or agents that reduce glucose output (e.g. fructose 1,6-bisphosphatase inhibitors) are receiving attention.
- Sodium-glucose co-transporter-2 (SGLT2) inhibitors act independently of insulin to eliminate excess glucose via the urine.

Introduction

This chapter reviews recently approved and prospective agents for the treatment of hyperglycemia, including agents in early clinical development and preclinical compounds that indicate potential new therapeutic approaches. The main focus is towards T2DM where differently acting therapies are required to address the clinical heterogeneity that results from multivariable genetic and environmental factors and a progressive natural history [1].

Moreover, the spectrum of complications and comorbidities associated with T2DM restricts treatment options, especially at more advanced stages, and best management with currently available agents is often unable to reinstate and sustain metabolic normality and avoid or contain complications [2,3].

Approaches to new antidiabetic agents

While looking to the future, this chapter acknowledges the value of integrating new therapies into the existing framework of treatments for T2DM [3,4]. Thus lifestyle measures provide the foundation upon which drug treatments are added, noting that early interventions to address endocrine and metabolic disturbances, limit gluco- and lipotoxicity, and provide comprehensive cardiovascular risk reduction are all important to achieve long-term benefits. Because diabetes is a lifetime imposition, therapies must have a good safety profile, be well tolerated and easily administered, and carry minimal risk of serious hypoglycemia [5]. Ideally, new therapies will counter the progressive decrements in metabolic control and offer novel mechanisms with additive efficacy when used in combination with other agents. Other benefits sought include weight control and pharmacokinetic properties that favor use in vulnerable groups such as the elderly and frail, or those with renal, liver, neuropathic or cardiovascular diseases.

The preclinical and clinical phases of drug development from discovery to marketing authorization are summarized in Table 47.1. The process may take 10–15 years and cost US$ 500–2000 million, with most expenditure during the phase 3 clinical trials. Additional trials may be required after marketing authorization, usually as part of a pharmacovigilance program, and further studies may be designed to acquire new indications, develop new formulations or add single-tablet fixed-dose combinations or single-injection combinations [5].

To provide structure to this review, new blood glucose-lowering agents have been organized according to their main

Table 47.1 Stages in the development of a new drug

Preclinical stages

New chemical entity (NCE)

Preclinical phases	• Identification, extraction/synthesis, chemical characterization and patenting of compounds • Genotoxicity testing. Screening for biologic activity *in vitro* and *in vivo* in animals • Preclinical pharmacology, mode of action, pharmacodynamics (activity, safety, tolerance), pharmacokinetics (bioavailability, distribution, metabolism, elimination) and toxicity in $\geq$2 mammalian species

Clinical stages

Investigational new drug (IND) application: permission to begin clinical studies

Phase 1	• First administration to a small number of healthy human volunteers. Dose ranging, vital signs, pharmacodynamics, pharmacokinetics, drug interactions, safety
Phase 2	• First trials in small numbers of patients. Dose ranging, efficacy, further pharmacodynamics, pharmacokinetics, and safety
Phase 3	• Trials in larger numbers of patients. Multicenter trials, comparative trials with other treatments, efficacy, further pharmacodynamics, and safety (including meta-analysis of cardiovascular outcomes)

New drug application (NDA): permission to market as a drug

Phase 4	• Use in medical practice. Additional trials (similar to phase 3), postmarketing surveillance, adverse events reporting, use in special subgroups (e.g. elderly and frail people)

mode or site of action. Principal actions are to enhance insulin secretion or suppress glucagon secretion, improve insulin sensitivity, independently suppress hepatic glucose output, impair counterregulatory mechanisms, delay carbohydrate digestion and intestinal glucose absorption, modulate lipid metabolism or adipose tissue activity, or directly promote glucose metabolism or increase renal glucose elimination (Figure 47.1). For comparison, and to indicate opportunities for complementary and additive use, the main actions of existing agents are summarized in Table 47.2.

Inhibitors of intestinal carbohydrate digestion and absorption

Fiber-rich diets and fiber supplements slow the digestion and absorption of dietary carbohydrate, reducing postprandial hyperglycemia while often reducing insulin concentrations. Soluble fibers such as gums, pectins, and hemicelluloses appear to be more effective than insoluble fibers such as celluloses and wheat bran, providing a greater barrier for diffusion of digestive enzymes and liberated saccharides. However, soluble fibers such as the galactomannan guar gum (E412) and fruit pectins are already common food thickeners, and normal balanced diets with fruits and vegetables should contain plenty of fiber. The effect of further fiber is generally modest, although glucomannan soluble fibers supplements are widely used. It is noted that fiber-rich diets can be used in conjunction with any antidiabetes

drug therapy to reduce prandial hyperglycemic excursions, and they may usefully reduce interprandial hypoglycemia in insulin-treated patients [6].

Slowing carbohydrate digestion with reversible competitive inhibitors of α-glucosidase enzymes, such as acarbose, miglitol and voglibose, reduces postprandial hyperglycemia and often reduces insulin concentrations in individuals who consume a diet rich in complex carbohydrate (Figure 47.2). Inhibitors of α-amylase enzymes have been considered as agents to slow the hydrolysis of dietary starch, but the effects have been too unpredictable for routine therapeutic use, running the risk that undigested sugars might enter the large bowel and undergo fermentation [6].

Initiators of insulin secretion

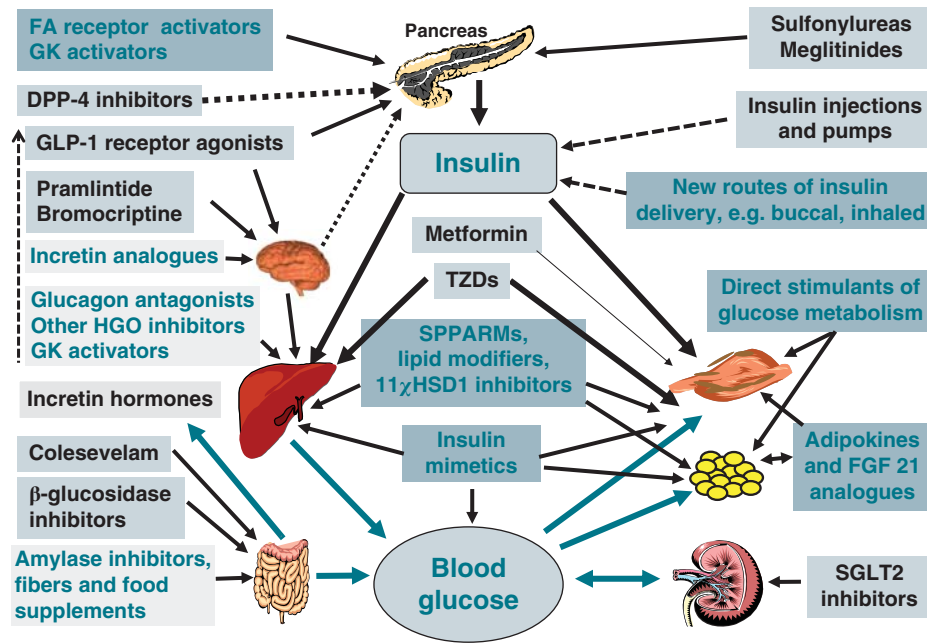
The progressive decline of β-cell function in T2DM involves loss of the acute first-phase insulin secretory response to glucose, impaired processing of proinsulin to insulin, an abnormal pulsatile rhythm of basal insulin secretion, and an extended second phase of glucose-induced insulin secretion that diminishes in magnitude as the extent of postprandial hyperglycemia increases (see Chapters 24 and 25). In advanced stages of T2DM there are also reductions in β-cell mass and insulin biosynthesis [1]. Insulin secretagogues can be categorized into *initiators* (e.g. sulfonylureas), which stimulate insulin secretion on their own or require only low glucose concentrations, and


Figure 47.1 Potential sites of action of blood glucose-lowering agents. 11βHSD-1, 11β hydroxysteroid dehydrogenase-1; DPP-4, dipeptidyl peptidase-4; FA, fatty acid; FGF 21, fibroblast growth factor 21; GK, glucokinase; GLP-1, glucagon-like peptide-1; HGO, hepatic glucose output; SPPARMs, selective peroxisome proliferator-activated receptor modulators; SGLT2, sodium-glucose co-transporter-2; TZDs, thiazolidinediones.

potentiators (e.g. GLP-1 receptor agonists), which enhance the effect of raised concentrations of glucose and other initiating secretagogues but do not initiate insulin release on their own.

K$_{ATP}$ channel closers

The biochemical route map within the islet β cell through which glucose stimulates insulin secretion is illustrated in Figure 47.3. Sulfonylureas and meglitinides activate this route part way along by binding to the so-called sulfonylurea receptor-1 (SUR1) in the plasma membrane. SUR1 is part of the adenosine triphosphate (ATP)-sensitive potassium channel (K$_{ATP}$ channel) comprising an octameric complex of four Kir6.2 pore-forming complexes (inwardly-rectifying potassium channels) surrounded by four SUR1 molecules. Although sulfonylureas and meglitinides bind at different sites on SUR1 the effect is much the same as binding of ATP to the nucleotide-binding domains, namely to close the Kir6.2 pore [7]. This prevents K$^+$ efflux, causing localized depolarization of the plasma membrane which opens voltage-gated (L-type) calcium channels. The ensuing influx of Ca^{2+} ions increases the cytosolic calcium ion concentration which activates calcium-sensitive proteins that trigger the exocytosis of insulin-containing secretory granules. SUR1–Kir6.2 channels are also located within the membranes of mitochondria and possibly other organelles, suggesting that sulfonylureas and meglitinides could act at these sites to influence insulin release. Since this insulin secretory mechanism can operate at low glucose concentrations it carries

a risk of interprandial hypoglycemia, whereas an ideal insulin secretagogue would restore β-cell sensitivity to raised glucose and support adequate biosynthesis, processing and secretion of insulin without stimulating insulin secretion at low glucose concentrations.

Several different types of compounds that close K$_{ATP}$ channels have been considered as potential new insulin secretagogues. Only the meglitinide derivative mitiglinide (KAD-1229) has proceeded through clinical development, receiving approval for routine use in some countries [6]. Other compounds that close K$_{ATP}$ channels such as the morpholinoguanidine BTS67582 and certain imidazolines have not proceeded beyond early clinical studies, although several of the imidazolines also bind to I1, I2 and probably other receptors, which may be involved in insulin secretion. There are also imidazolines such as BL11282 that stimulate glucose-induced (but not basal) insulin secretion independently of K$_{ATP}$ channels, probably via effects on protein kinases. Some nonselective alpha2-adrenergic receptor antagonists such as phentolamine, which can reduce the tonic suppression of insulin secretion mediated through alpha2-adrenergic activation, may also act to close K$_{ATP}$ channels [6].

Although closure of K$_{ATP}$ channels initiates insulin secretion it does not increase proinsulin biosynthesis. Since increased nutrient metabolism within the β cell will increase proinsulin biosynthesis and close K$_{ATP}$ channels via increased ATP production, the stimulation of mitochondrial nutrient metabolism has been evaluated as a potential route to increase insulin

Table 47.2 Existing agents with approved indications as blood glucose-lowering agents

Class and examples	Main mechanisms of action
Oral	
Biguanide _Metformin_	Reduce hepatic glucose production, improve insulin action, increase gut-liver glucose cycling and other insulin-independent effects
Sulfonylureas _Glibenclamide_ _(Glyburide)_ _Gliclazide_ _Glimepiride_ _Glipizide_ _Tolbutamide_	Stimulate insulin secretion by binding to SUR-1 on β cells and closing K_{ATP} channels (effect typically lasts 6–24 h)
Meglitinides (Prandial insulin releasers, meglitinides) _Mitiglinide_ _Nateglinide_ _Repaglinide_	Stimulate insulin secretion by binding to SUR-1 on β cells at a different site to sulfonylureas and closing K_{ATP} channels (rapid effect, typically lasts <6 h)
DPP-4 inhibitors (Gliptins) _Alogliptin_ _Linagliptin_ _Saxagliptin_ _Sitagliptin_ _Vildagliptin_	Inhibit enzyme dipeptidyl peptidase-4 prolonging circulating half-lives of some incretin hormones such as GLP-1 which enhance prandial insulin secretion and exert other glucoregulatory effects
Thiazolidinediones (Glitazones. TZDs) _Pioglitazone_ _Rosiglitazone_	Improve insulin sensitivity mainly via activation of peroxisome proliferator-activated receptor-γ (PPARγ)
SGLT2 inhibitors _Canagliflozin_ _Dapagliflozin_ _Empagliflozin_	Inhibit mainly renal sodium-glucose co-transporter 2 to enable increased glucose elimination in the urine
Alpha-glucosidase inhibitors _Acarbose_ _Miglitol_ _Voglibose_	Slow rate of carbohydrate digestion
Dopamine agonist _Bromocriptine_	Improve circadian rhythmicity of glycemic control with suppression of hepatic glucose production
Bile sequestrant _Colesevelam_	Possibly alter secretion of incretin hormones such as GLP-1
Subcutaneous injection	
GLP-1 receptor agonists _Exenatide_ _Liraglutide_ _Lixisenatide_	Activate GLP-1 receptors, mimic action of GLP-1 to enhance prandial insulin secretion, reduce prandial glucagon secretion, delay gastric emptying and exert satiety effect
Amylin analogue _Pramlintide_	Slow gastric emptying, suppress glucagon secretion, possible satiety effect

Table 47.2 (_continued_)

Class and examples	Main mechanisms of action
Insulin Rapid-acting: _Aspart, Glulisine,_ _Lispro_ Short-acting: _Actrapid, Humulin S,_ _Insuman Rapid_	Reduce hepatic glucose output Increase peripheral glucose uptake Increase glucose metabolism Decrease lipolysis Increase lipogenesis Favor protein anabolism
Intermediate: _Insulatard, Humulin I_	
Long-acting: _Degludec, Detemir,_ _Glargine_ Biphasic (pre-mixed): _Humalog, Humulin_ _M3, Novomix_	

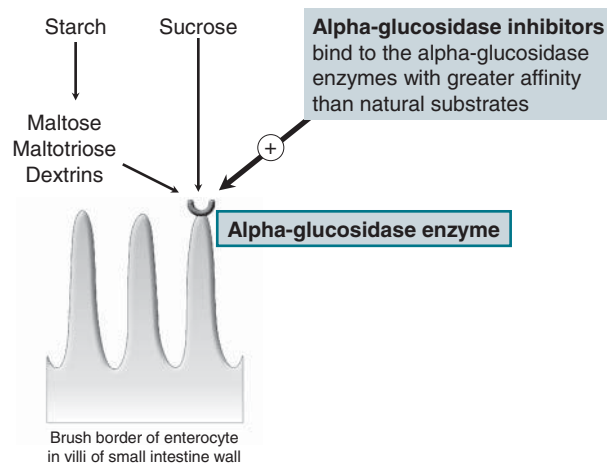
DPP-4, dipeptidyl peptidase-4; GLP-1, glucagon-like peptide-1; K_{ATP} channels, adenosine triphosphate-sensitive potassium channels; PPARγ, peroxisome proliferator-activated receptor-gamma; SGLT, sodium-glucose co-transporter; SUR-1, sulfonylurea receptor-1; TZDs, thiazolidinediones.


Figure 47.2 Alpha-glucosidase inhibitors slow carbohydrate digestion by competitive inhibition of α-glucosidase enzymes at the luminal surface of brush border membranes of enterocytes in the small intestine. Alpha-glucosidase inhibitors in present use are acarbose, miglitol, and voglibose. These agents have different affinities for specific α-glucosidases: the binding affinity of acarbose competitively inhibits glucoamylase > sucrase > dextrinase; miglitol and voglibose potently inhibit sucrase, while voglibose shows more potent inhibition of other α-glucosidases than acarbose. Acarbose also weakly inhibits alpha-amylase.

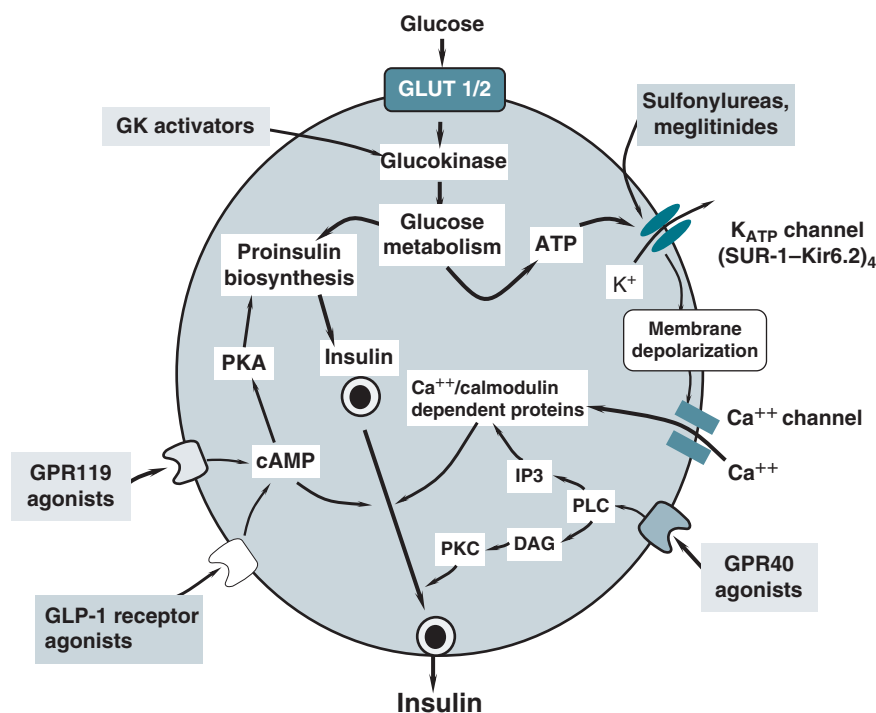
secretion alongside proinsulin biosynthesis. Succinate esters, for example, fulfil this role, but their low enteral bioavailability and short duration of action have precluded clinical development, and their propensity to fuel hepatic gluconeogenesis is a further deterrent. Stimulation of mitochondrial succinyl-coenzyme A (CoA) synthetase to generate ATP and guanosine triphosphate (GTP) has also been considered, but has proved difficult to specifically target the β cell [6].


Figure 47.3 Stimulus-secretion coupling pathways in the pancreatic β cell showing key mechanisms through which agents can initiate or potentiate insulin release. cAMP, cyclic adenosine monophosphate; DAG, diacylglycerol; GK, glucokinase; GPR, G-protein-coupled receptor; IP3, inositol-1,4,5-trisphosphate; PKA, protein kinase A; PLC, phospholipase C.

Glucokinase activators

The enzyme glucokinase (GK, EC 2.7.1.1) is expressed by islet β cells and hepatocytes where it phosphorylates glucose to glucose-6-phosphate. Since these cells can take up glucose (via the glucose transporters GLUT2, and GLUT1 in human islets) approximately in proportion to the circulating glucose concentration, GK constitutes the rate-limiting step for metabolism of glucose in these cells [8]. Thus GK activators have been considered as a therapeutic approach to enhance glucose metabolism in both cell types. This would enhance glucose-induced insulin secretion and proinsulin biosynthesis through ATP production by the β cells, and facilitate glucose utilization or glycogen storage in liver. Islet α cells also express GK which appears to assist the glucose-dependent suppression of glucagon secretion.

Several specific small molecule allosteric activators of GK (e.g. various acetamides and benzamides) have been shown to increase insulin secretion and improve glucose homeostasis in animal models of non-insulin-dependent diabetes [8]. Although this effect is actually potentiating the action of glucose, it can operate at low glucose concentrations, so the effect is similar to an initiator, and if this effect is not rapidly terminated when the glucose concentration subsides, there is a risk of continued insulin secretion and hypoglycemia.

Glucokinase is regulated slightly differently in the liver compared with islet β cells. In the liver GK becomes activated by the influx of glucose which slowly dissociates the enzyme from a regulatory binding protein, whereas islet cells do not express the binding protein [8]. Thus the action of GK in liver can be enhanced and prolonged by allosteric activators and by molecules that prevent association of GK with or cause dissociation of GK from its regulatory binding protein. Several such agents have been assessed in clinical trials but the tight therapeutic index to avoid hypoglycemia and the lack of durable efficacy have so far prevented completion of a development program. Liver-selective GK activators are being considered as a way of avoiding hypoglycemia, but the potential risk of excess liver glycogen and hepatic lipogenesis remains to be determined.

Potentiators of insulin secretion

Agents that potentiate nutrient-induced insulin secretion should act mainly to reduce postprandial hyperglycemia with less risk of interprandial hypoglycemia than agents that can initiate insulin secretion at low glucose concentrations.

Incretins

Incretin hormones are released from the gut during feeding and enhance nutrient-induced insulin secretion and suppress glucagon secretion. The main incretins are glucagon-like peptide-1 (GLP-1) and gastric inhibitory polypeptide (GIP; also known as glucose-dependent insulinotropic peptide). They appear to alter islet cell function partly via neural pathways activated during their passage through the portal circulation

Table 47.3 Glucoregulatory effects of glucagon-like peptide-1 (GLP-1) and gastric inhibitory polypeptide (GIP; also known as glucose-dependent insulinotropic peptide)

	GLP-1	GIP
Released in response to a mixed meal	Yes	Yes
Lower blood glucose	Yes	Yes
Glucose-dependent stimulation of insulin secretion	Yes	Yes
Suppress glucagon secretion	Yes	No
Extrapancreatic glucose-lowering actions	Yes	Yes
Extend β-cell mass and survival	Yes	Yes
Suppress gastric acid secretion	No	Yes
Inhibition of gastric emptying	Yes	No
Inhibition of hepatic insulin extraction	Yes	Yes
Enhance satiety	Yes	No
Reduce body weight	Yes	No

and partly via direct effects on the islets. G-protein coupled receptors (GPCRs) in the β-cell membrane, when activated by their incretin ligands, potentiate mainly glucose-induced insulin secretion and proinsulin biosynthesis through activation of adenylate cyclase, increasing production of cyclic adenosine monophosphate (cAMP) and protein kinase A (PKA) [9]. Effects on Ca^{2+} ion distribution within the islet β cells may also be involved. Both GLP-1 and GIP are reported to promote β-cell mass in animal models, possibly slowing β-cell apoptosis and increasing β-cell neogenesis by increased expression of the transcription factor pancreatic duodenal homeobox-1 (PDX-1), which promotes proliferation and differentiation of ductal progenitor cells. However, these latter effects on β-cell mass have not been confirmed in human diabetes.

Significantly impaired secretion of GLP-1 or GIP has not been consistently observed in T2DM, but the potentiation of glucose-induced insulin secretion in T2DM with pharmacologic doses of GLP-1 remains stronger than with GIP, which accounts in part for the therapeutic use of GLP-1 rather than GIP. Other properties of GLP-1 are very important: GLP-1 suppresses glucagon secretion in a glucose-dependent manner, slows gastric empting, and exerts a satiety effect that can facilitate weight loss (Table 47.3). However, rapid degradation of GLP-1, mostly by the enzyme dipeptidyl peptidase-4 (DPP-4) and the renal clearance of GLP-1 (plasma half-life <2 min) limits use of the peptide itself as a form of therapy [9,10].

GLP-1 receptor agonists

DPP-4 cleaves the N-terminal dipeptide if there is an Ala residue (as in GLP-1) or Pro residue at the N2 position. Of the currently available GLP-1 receptor agonists, exenatide (exendin-4) and lixisenatide are GLP-1 analogues with a Gly residue at the N2 position and substitutions at other positions (Figure 47.4), making these molecules resistant to degradation by DPP-4 and endopeptidases, thereby extending the circulating half-life to several hours. Liraglutide is GLP-1 (7-37) with Lys34 replaced by Arg34, and Lys26 attached via a glutamate residue to a C16 hexadecanoyl (palmitoyl) fatty acid chain. The fatty acid chain attaches to albumin, protecting against degradation by DPP-4 [10,11].

Each of these molecules retains a strong affinity for the GLP-1 receptor and is delivered by subcutaneous injection. Exenatide is given twice daily before the main meals or as a once-weekly depot formulation in which the molecule is embedded within polylactide-glycolide microspheres. Lixisenatide is given once or twice daily and liraglutide once daily. The glucose-dependent nature of the insulin-releasing and glucagon-suppressing effects is reflected in the limited risk of hypoglycemia, while the satiety effect has assisted weight loss and favors use in obese patients. Nausea related to the delayed gastric emptying is not uncommon as a temporary early side effect. Several further once-weekly and potentially longer lasting injectable GLP-1 analogues are advanced in clinical trials: for example albiglutide is two GLP-1 analogues linked to albumin, while dulaglutide is two GLP-1 analogues linked to IgG. Depot formulations releasing GLP-1 analogues over one or several months have also entered clinical trials, and noninjected routes of administration of GLP-1 analogues including transdermal, buccal and inhaled are being explored [11,12].

GIP analogues

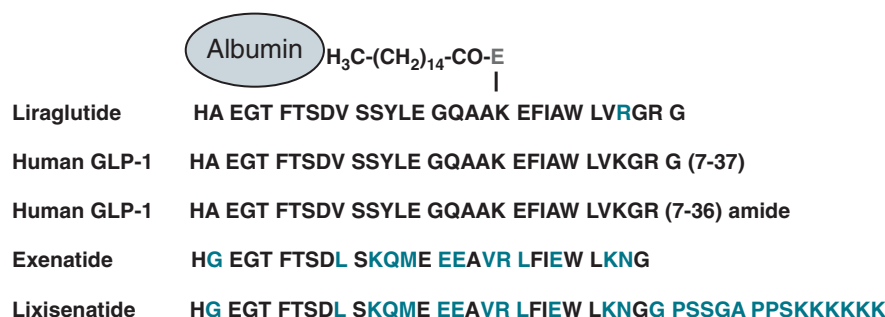
Although GIP potentiates nutrient-induced insulin secretion it also increases glucagon release and promotes lipid deposition. Several DPP-4-resistant GIP analogues have been shown to modestly improve glucose control without weight


Figure 47.4 Peptide sequences of GLP-1 and GLP-1 receptor agonists.

reduction [13]. However, neutralization of GIP with GIP antisera or GIP receptor knockout and pharmacologic GIP receptor blockade have prevented the development of obesity, improved glucose homeostasis and reduced insulin resistance in animal models. This is consistent with evidence from bariatric surgery that reduced nutrient supply through the proximal small intestine (location of GIP-secreting K-cells) contributes to glycemic control in obese diabetic patients. Thus GIP analogues that antagonize GIP receptors, or selective monoclonal antibody antagonists or nonpeptide antagonists may offer a pharmacologic opportunity to mimic some of the effects of bariatric surgery.

Combinatorial, chimeric, and hybrid peptides

Given the potential for combination of GLP-1 with either a GIP agonist or antagonist, combinatorial (linked) native or analogue versions of these peptides have been evaluated. In general these have shown little additional benefit beyond that of a GLP-1 receptor agonist alone, but the concept of combining two or more peptides into a single molecule is now receiving wider therapeutic attention [14].

Like GLP-1, some other incretins show homology or commonality through precursor biosynthesis with glucagon. While glucagon is well known to increase hepatic glucose production (and the potential of glucagon receptor antagonists is considered later), glucagon also assists weight loss through reduced meal size, increased lipolysis, and increased energy expenditure. Oxyntomodulin, derived from preproglucagon, is a weak agonist of receptors for GLP-1 and glucagon, suppressing food intake, increasing energy expenditure, and illustrating a naturally occurring form of combination. For pharmacologic extension of this overlap, chimeric peptides (part GLP-1 agonist, part glucagon agonist) and hybrid peptides (design based on selected partial sequences of GLP-1 and glucagon) have been constructed with strong GLP-1 receptor agonism and weaker glucagon agonism. These have shown potentiation of glucose-induced insulin secretion and weight loss while overriding the hyperglycemic effect of glucagon. Duration of patency of the molecules has been prolonged by avoiding an N-terminal sequence susceptible to DPP-4 and by conjugation to polyethylene glycol. Since some effects of glucagon may be facilitated by fibroblast growth factor 21, this has also been considered as an addition [14].

Nonpeptide incretin mimetics

The clinical application of large peptides implies parenteral (probably subcutaneous) administration, and peptides raise questions regarding long-term antibody production, attenuated responses to native hormones and receptor downregulation. To address some of these issues development of nonpeptide small molecule incretin receptor agonists and antagonists is being considered. For example, nonpeptide GLP-1 receptor agonists bind to GLP-1 receptors on islet β cells and enhance glucose-dependent insulin secretion in animals, while a GIP antagonist has been shown to counter obesity and insulin resistance in animals [13,15].

DPP-4 inhibitors

Agents that inhibit the enzyme DPP-4 (EC 3.4.14.5) prevent rapid inactivation of GLP-1 and GIP, raising their circulating concentrations and thereby enhancing their effects [10,16]. Current DPP-4 inhibitors ("gliptins") include sitagliptin, vildagliptin, saxagliptin, linagliptin, and alogliptin (see Chapter 48). Although there are subtle pharmacokinetic differences, therapeutic use of each of these agents will produce almost complete inhibition of DPP-4 activity for most of a 24-h period, and they each improve glycemic control without weight gain. Their effects are attributed largely to increased concentrations of GLP-1 which are raised about two- to threefold, although it is noted that DPP-4 inhibition may also raise GIP concentrations. For comparison, injected GLP-1 receptor agonists generate circulating values equivalent to about 10-fold higher than endogenous GLP-1. These differences could explain why DPP-4 inhibitors do not consistently produce the magnitude of effects of injected GLP-1 receptor agonists and do not cause significant weight reductions. However, DPP-4 inhibitors do not cause initial nausea through delayed gastric emptying.

DPP-4 exists unattached in the circulation and tethered to cell membranes especially of endothelia in capillaries of the gastrointestinal tract. The protease activity of DPP-4 degrades a range of biologically active peptides in addition to incretins, where there is an N2 Ala or Pro. Susceptible peptides include substance P, bradykinin, peptide YY, neuropeptide Y, pituitary adenylate cyclase-activating peptide, insulin-like growth factor-1, and various interleukins and monocyte chemo-attractant proteins [16,17]. Despite affecting this wide range of peptides, to date DPP-4 inhibitors have not shown significant adverse effects during substantial clinical use. Also, DPP-4 is the lymphocyte cell surface protein CD26 required for the co-stimulation response to recall antigens, but its immunologic role does not appear to be interrupted by small molecule inhibitors of its peptidase activity. This lack of interference with other biologic functions has prompted development of long-acting (e.g. once-weekly) DPP-4 inhibitors such as MK-3102 [18].

Fatty acid receptor agonists

Pancreatic β cells take up fatty acids which serve as metabolic substrates: acutely they enhance insulin secretion, but chronic exposure to raised fatty acid concentrations within the cell causes detrimental lipotoxic effects. In addition to these effects certain fatty acids serve as ligands for GPCRs in the β-cell membrane. Binding to these receptors does not give a fatty acid access to the cell, but activates the GPCRs to generate intracellular signals that influence insulin secretion, mainly by actions that potentiate insulin secretion that is initiated by other factors [19]. The principal fatty acid-activated GPCRs of the β cells are GPR40 (FFAR1) and GPR119, and synthetic ligands

have been developed to activate the receptors and potentiate glucose-induced insulin secretion.

Ligand binding to GPR40 activates a subunit of the receptor that signals via phospholipase C (PLC) to enhance insulin secretion by raising intracellular Ca^{2+} partly by mobilizing Ca^{2+} from endoplasmic reticulum and partly by increasing Ca^{2+} influx across the cell membrane (Figure 47.2). Additionally the PLC increases diacylglycerol which acts via isoforms of protein kinase C to increase distal steps in the exocytotic pathway. Ligand binding to GPR119 activates a subunit of the receptor that signals via adenylate cyclase to enhance cyclic adenosine monophosphate and protein kinase A as described earlier for incretins. GPR40 and 119 are expressed on intestinal L cells that secrete GLP-1, enabling synthetic ligands to further enhance insulin secretion via increased GLP-1. However, GPR40 and especially GPR119 are expressed by islet α cells, where they could mediate increased glucagon secretion [19,20].

Other insulin secretion potentiators

Tetrahydrotriazine-containing compounds, notably imeglimin, enhance glucose-induced insulin secretion and may reduce β-cell apoptosis. Additionally imeglimin acts on liver to reduce gluconeogenesis and on skeletal muscle to promote glucose uptake. Several phosphodiesterases, particularly isoform PDE-3B, are expressed by islet β cells, degrading cAMP and reducing insulin release. Selective and transient inhibition of this isoform is a possible intervention but difficult to target specially to β cells. Antagonism of alpha2-adrenoceptors remains another possibility [6].

Increasing insulin action

Impaired insulin action (insulin resistance) is an early and sustained feature of most presentations of adult-onset T2DM. Hence new interventions are sought to improve insulin receptor and postreceptor signaling, or to act independently of insulin to address disturbances of substrate transporters, metabolic enzymes, and other abnormalities that give rise to gluco- and lipotoxicity [21]. It is noted that although some of the metabolic consequences of insulin resistance can be relieved by interventions that are independent of insulin, a basal level of insulin action is required for the genomic effects that determine expression levels for many of the cellular components that directly and indirectly control metabolic homeostasis. Excess proinsulin and insulin-like growth factor-1 represent prereceptor factors contributing to insulin resistance because they bind weakly to the insulin receptor and generate a much lesser response than insulin. Defects of insulin receptor structure are uncommon, and reductions in insulin receptor numbers are not usually rate limiting, suggesting that interventions are required to enhance insulin receptor signaling and early postreceptor signaling defects in order to increase the spectrum of insulin effects. However, rate-limiting defects can occur at more distal locations and negative feedbacks can operate that limit the full transmission of improvements at early steps in the signaling pathways. Also, most of the postreceptor pathways are not specific to insulin and impact activities as disparate as cell differentiation and apoptosis. Thus many potential sites are being explored to enhance insulin action (Figure 47.5), bearing in mind that they should circumvent rate-limiting bottlenecks without distorting the overall equanimity of signaling balance across many cellular functions [22].

Initiating insulin receptor activity

Therapeutic activation of the insulin receptor is presently achieved with insulin, insulin analogues and related peptides, but a convenient advance would be the replacement of these agents with small nonpeptide compounds that could be administered orally. The fungal metabolite demethylasterriquinone provided initial evidence for a nonpeptide insulin mimetic. Low concentrations (3–6 uM) of demethylasterriquinone initiated phosphorylation and tyrosine kinase activity of the B-subunit of the human insulin receptor expressed in Chinese hamster ovary (CHO) cells [23]. This in turn induced tyrosine phosphorylation and activation of insulin receptor substrate-1 (IRS1), with downstream activation of phosphatidylinositol 3-kinase (PI3K) and Akt (protein kinase B). Studies with mutated A-subunits of the insulin receptor showed that demethylasterriquinone interacted selectively with the B-subunit (without requiring insulin to bind to the A-subunit), and its activity could not be attributed to inhibition of protein tyrosine phosphatases. Demethylasterriquinone produced a range of insulin-like effects in normal tissues including increased glucose uptake by isolated rodent adipocytes and skeletal muscle, and orally administered doses of $5-25\,mg\,kg^{-1}\,d^{-1}$ lowered blood glucose in insulin-resistant obese diabetic *db/db* mice. Various features of demethylasterriquinone are not suited to clinical development but this molecule has provided evidence for the concept for an orally active small molecule insulin mimetic. Although the low affinity binding of proinsulin and insulin-like growth factor-1 (IGF-1) to the insulin receptors can impede the effectiveness of native insulin, therapeutic advantage has been taken of cross-talk between the IGF-1 receptor and early postreceptor components of the insulin-signaling cascades to treat some rare cases of severe insulin resistance caused by genetic defects of the insulin receptor. However, extra amounts of IGF-1 carry the caution of potential proliferative and other effects, although overly raised peak concentrations of free circulating IGF-1 after subcutaneous administration have been limited by concomitant administration of the binding protein IGFBP-3 [6].

Small variations in the metabolic responses to different insulin-related peptides suggest that subtle differences in binding at the receptor A-subunit can modulate the profile of signaling activities of the B-subunit [24]. Selective insulin receptor modulation might be used to avoid potential mitogenic effects associated with activation of IGF-1 receptors. For example a monoclonal antibody has been developed that binds

specifically to the insulin receptor and produces predominantly metabolic effects of insulin [25].

Potentiating insulin receptor activity

Binding of insulin to the A-subunit of the insulin receptor produces conformational changes that enable tyrosine phosphorylation of the B-subunit. Therapeutic agents that interact with the B-subunit to augment or prolong its tyrosine phosphorylation have therefore been sought, and nonpeptide molecules that achieve this have been shown to enhance insulin action, such as TLK16998 [26].

Co-administration of insulin C-peptide together with insulin augments the metabolic effects of insulin, and there is evidence from studies in isolated liver and muscle cells that the C-peptide may enhance insulin receptor tyrosine kinase activity and phosphorylation of IRS1 and other postreceptor signaling intermediates [27].

Protein tyrosine phosphatase-1B inhibitors

Several protein tyrosine phosphatases (PTPs), especially PTP-1B, dephosphorylate the B-subunit of the insulin receptor and so terminate its tyrosine kinase activity [28]. These phosphatases also dephosphorylate and deactivate the insulin receptor substrates IRS1 and IRS2, whereas PTP-1B knockout mice and antisense oligonucleotides against PTP-1B increase insulin sensitivity. As proof of concept, several selective small molecule inhibitors of PTP-1B have improved glycemic control in insulin-resistant diabetic animals [29]. Inhibiting PTP-1B may also assist weight control by increasing the satiety effect of leptin receptor signaling, and improve endothelial function by improving insulin-induced endothelial nitric oxide synthase (eNOS) production [6]. Vanadium salts (reviewed later) inhibit PTP-1B, and have been shown to enhance the actions of insulin and possibly leptin.

Inhibition of negative feedback signals

Early components of postreceptor signaling pathways of insulin action involve phosphatidylinositol-3,4,5 trisphosphate (PIP3) and phosphoinositide-dependent kinases PDK-1/2. These signaling intermediates activate certain isoforms of protein kinase C (PKC) such as PKC-theta which exerts a negative feedback by phosphorylation of a serine on the insulin receptor B-subunit and on IRS-1, preventing tyrosine phosphorylation and reducing kinase activity. Thus, inhibition of specific isoforms of PKC provides a potential means to improve insulin action, but developing highly selective inhibitors has proved difficult [6,22].

Other serine kinases that interfere with the tyrosine kinase activity of the insulin receptor B-subunit and IRS proteins are potential therapeutic targets. These include inhibitor kappa-B kinase-beta (IKKB) and c-Jun N-terminal kinase (JNK) which contribute to the insulin resistance produced by the cytokine tumor necrosis factor-alpha. Agents that suppress these serine kinases (e.g. salicylates inhibit IKKB) can partly relieve insulin resistance. The insulin signaling intermediate Akt activates the mammalian target of rapamycin (mTOR) which exerts a negative feedback on IRS proteins through serine phosphorylation, and the membrane ectoenzyme glycoprotein-1 (PC-1/NNP1) binds to the insulin receptor and prevents the conformational changes required for receptor autophosphorylation [6,22]. These interactions present potential sites for therapeutic intervention, though it is difficult to envisage selective interference that would not impinge on other regulatory pathways.

Potentiation of postreceptor signals

The phosphorylation of phosphatidylinositol 4,5-bisphosphate (PIP2) to the 3,4,5-trisphosphate (PIP3) by phosphatidylinositol 3-kinase (PI3K) is often reduced in insulin-resistant states, and increased availability of precursor inositol substrates may improve this step. Thus, D-*chiro*-inositol (INS-1) and the 3-methoxy analogue of D-*chiro*-inositol (pinitol) improve muscle glucose uptake and reduce hyperglycemia in diabetic animal models and type 2 diabetes patients [22]. D-*chiro*-inositol-galactosamine (INS-2) also increased insulin action in diabetic rats, possibly involving activation of pyruvate dehydrogenase phosphatase (protein phosphatase 2C; PP2C).

Another approach could be to prevent the dephosphorylation of PIP3. The phosphatase PTEN which dephosphorylates PIP3 can be inhibited by an antisense oligonucleotide which increases signaling downstream of PIP3, and improves insulin sensitivity and glycemic control in insulin-resistant animal models [30]. PIP3 is also dephosphorylated by the phosphatase SHIP-2, and partial disruption of the SHIP-2 gene in mice improves insulin sensitivity. However, interference with PIP3 dephosphorylation may disturb pathways that could carry a risk of tumor formation.

Adipokines

Several of the autocrine, paracrine, and endocrine factors produced by adipose tissue affect insulin action and have been considered as targets or templates for therapeutic agents (Figure 47.6) [31]. For example, adipose tissue is a source of pro-inflammatory cytokines such as TNF-alpha and interleukin-6 (IL6), which impair insulin receptor B-subunit tyrosine kinase activity through JNK, IKKB, and the suppressor of cytokine signalling-3 (SOCS-3) (Figure 47.5). However, these cytokines exert other effects that may influence glucose homeostasis, and antibodies to IL6 and TNF-alpha have shown limited efficacy as treatments for diabetes and may increase susceptibility to infection.

Adipocyte hormones

Of the many adipocyte hormones, leptin and adiponectin have received most attention as possible diabetes therapies.

Leptin

The centrally mediated satiety and thermogenic effects of leptin which facilitate weight loss, and direct peripheral effects of
Figure 47.6 Secretions of adipose tissue that have been considered as potential targets or templates for therapeutic agents to improve glycemic control. IL6, interleukin-6; RBP4, retinol-binding protein-4; TNF-α, tumor necrosis factor alpha.

leptin to improve insulin action and possibly suppress glucagon, have made this peptide and its analogues and fragments potential treatments for obesity and diabetes. However, the development of leptin resistance and leptin antibodies has so far compromised long-term efficacy [32].

Adiponectin (Acrp30)
Because adiponectin increases insulin sensitivity, improves vascular reactivity and exerts anti-inflammatory activity, it appeals as a therapeutic template. Its presence in large amounts and with different circulating isoforms makes use of the native peptide difficult, but fragments and nonpeptide receptor agonists are under investigation [33,34].

Resistin (FIZZ3)
This adipocyte and macrophage hormone reduces insulin sensitivity, increases pro-inflammatory cytokines and exerts several adverse vascular effects. Since immunoneutralization of resistin has improved insulin sensitivity in rodents, inhibition of resistin action is being considered as a therapeutic approach [35].

Retinol-binding protein 4 (RBP4)
Several binding proteins that transport plasma retinoids are produced by adipocytes and liver. Increased RBP4 has been noted in the early stages of insulin resistance and obese states, and RBP4 gene knockout increases insulin sensitivity in animals, suggesting that a reduction of RBP4 might be considered to reduce the initial development of insulin resistance [36].

Visfatin, vaspin, omentin, and apelin
Each of these adipocyte peptides has recently been reported to improve insulin action, but their therapeutic potential is not clear. Visfatin derives mainly from visceral adipocytes, and appears to activate insulin receptors, increase insulin secretion, and alter expression of several genes linked to diabetes, but clinical studies have not shown a correlation between plasma visfatin and insulin sensitivity. Vaspin (visceral adipose tissue-derived serpin), omentin, and apelin have been reported to increase insulin-stimulated glucose disposal in obese insulin-resistant rodents and isolated cells [31,37].

Fibroblast growth factor 21

Fibroblast growth factor 21 (FGF21), a peptide secreted mostly from liver, muscle and adipose tissue, plays an important role during starvation by promoting hepatic gluconeogenesis, fatty acid oxidation, and ketogenesis. Pharmacologic doses of FGF21 administered to obese diabetic animals enhance insulin sensitivity, reduce hyperglycemia (despite increased gluconeogenesis), promote energy expenditure and weight loss, and improve the blood lipid profile without any apparent mitogenic activity. Although plasma FGF21 concentrations may be raised in human obesity and T2DM, indicating possible FGF21 resistance, clinical studies have noted that administration of FGF21 analogues can improve the lipid profile and produce a modest glucose-lowering effect [38]. Recent evidence indicates that FGF21 may improve insulin action via increased adiponectin secretion, and it is noted that FGF21 and adiponectin stimulate PPARγ, as described for thiazolidinediones [39].

Selective PPAR modulators

Agonists of the nuclear receptor peroxisome proliferator-activated receptor-gamma (PPARγ), such as the current thiazolidinediones (pioglitazone and rosiglitazone), increase insulin sensitivity. Stimulation of PPARγ alters transcription of various genes that mediate metabolic effects of insulin, increase adipogenesis, improve biomarkers of vascular function and exert anti-inflammatory actions (Figure 47.7) [40]. Different PPARγ agonists appear to alter the conformation of the PPARγ binding epitope or adjacent regions of the receptor in slightly different ways such that different co-activators are recruited, varying the selection of genes transcribed and therefore the profile of biologic effects. In addition to further thiazolidinediones, some nonthiazolidinedione PPARγ agonists have been described, including agents that partially modulate PPARγ such as halofenate/metaglidasen and FK614. The differing sets of genes activated by these agonists illustrate the possibility of selective PPARγ modulation to retain desired therapeutic effects and reduce side effects [41]. Selective effects can also be achieved by stimulating genes for particular co-activators such as PGC-1α.

A further approach to selective PPAR modulation has been the development of compounds that bind both PPARγ and PPARα (so-called dual PPARα/γ agonists, or "glitazars"), although previous glitazars (e.g. muraglitazar, tesaglitazar, and aleglitazar) have been discontinued due to side effects. Following evidence that stimulation of PPARδ can improve insulin sensitivity, increase fatty acid oxidation, raise thermogenesis, and prevent weight gain, agents have been sought with variable affinities for PPARα, γ, and δ (termed panPPAR agonists or SPPARMs—selective PPAR modulators) [41]. Some modulators of the retinoid X receptor, which forms a heterodimer with each PPAR, have been reported to reduce hyperglycemia, reduce
Figure 47.7 Mechanism of action of peroxisome proliferator-activated receptor modulators. Peroxisome proliferator-activated receptor (PPAR) ligands bind to nuclear PPAR receptors. There are three main types of PPAR receptor (PPARα, PPARγ, and PPARδ). Each activated receptor forms a heterodimer with the retinoid X receptor (RXR). Ligand binding releases repressors, attracts co-activators such as PPAR co-activator-1alpha (PGC-1α) and exposes the active site of the receptor which binds with a specific DNA nucleotide sequence (AGGTCAXAGGTCA) termed the peroxisome proliferator response element (PPRE). RNA polymerase is recruited and transcription of mRNA is increased (or sometimes decreased) for genes that carry the PPRE sequence in a promoter region. The mRNA is translated into the enzymes and transporters that bring about the biologic effects of PPAR ligands. Stimulation of different PPAR receptors by different ligands causes slightly different conformational changes of the receptors. This alters the binding of co-activators which alters the expression of different genes, giving rise to the diverse effects of PPAR ligands. FA, fatty acid; TG, triglyceride; HDL, high-density lipoprotein; ↑, increase; ↓, decrease.

appetite, increase production of mitochondrial uncoupling proteins, and decrease weight gain; combining these agents with PPARγ agonists is also receiving consideration.

Vitamins and minerals

Antioxidants are often depleted in diabetic states, and supplements of antioxidant vitamins have shown small benefits to glycemic control in some studies. Adequate vitamin D concentrations and functioning vitamin D receptors are required for normal activity of islet β cell and of insulin, and diabetes patients are often deficient in circulating vitamin D3 (cholecalciferol). Studies of vitamin D supplementation have so far been equivocal, but it should be borne in mind that correcting a deficiency state is more likely to offer benefit than adding excess in individuals who already have normal values [6,42].

Deficiencies of several minerals, particularly magnesium, chromium, and zinc are often observed in older diabetes patients, and replacement supplements can improve glycemic control in such cases [6]. Magnesium is required for phosphate transfer and kinase reactions, and supplements can enhance insulin action in hypomagnesemic patients. Trivalent chromium supplements can improve glycemic control without increasing insulin concentrations in chromium-deficient patients, and zinc, which is essential for insulin hexamer formation, assists in insulin secretion and action. Lithium, selenium, molybdenum, tungsten, mercury, and cadmium have all been reported to improve glycemic control, although the therapeutic index is generally narrow and toxicity risks have limited clinical investigations. Improved insulin sensitivity with lithium may be offset by decreased insulin secretion resulting in variable effects on glycemic control in T2DM.

Vanadium supplements have improved glycemic control and reduced insulin requirements in type 1 and type 2 diabetes patients, probably due in part to improved insulin sensitivity through inhibition of protein tyrosine phosphatases and suppression of glucose 6-phosphatase. Reduced appetite and a reduced rate of intestinal glucose absorption may also contribute. To limit potential toxicity low-dose peroxovanadium compounds, pervanadates, and organic vanadium complexes have been considered, and it has been noted that the glucose-lowering effects of vanadium salts can persist for weeks after treatment is stopped [6].

Inhibitors of counterregulatory hormones

The major counterregulatory hormones are glucagon and epinephrine which act acutely, and glucocorticoids and growth hormone which have a slower onset and generally more protracted action. They raise blood glucose concentrations by increasing hepatic glycogenolysis and gluconeogenesis, and by impairment of various metabolic effects of insulin. The circulating concentrations of counterregulatory hormones are often inappropriately raised in diabetic states, rendering them a treatment target. However, the counterregulatory response to low glucose concentrations is already delayed or deficient in advanced stages of T2DM, so it is important that interventions should not be so intensive or irreversible that they impede the response at low glucose concentrations.

Glucagon antagonists

Glucagon receptor antagonists have received considerable attention of late [43,44]. Improvements in glycemic control during suppression of glucagon action with glucagon antibodies or peptide antagonists of the glucagon receptor are well known but not particularly suited to routine clinical application. Now there are several small molecule glucagon receptor antagonists that have shown sufficient efficacy in preclinical studies to proceed into clinical trials. Although these are competitive inhibitors of glucagon binding there is also evidence that agents could be developed to uncouple the glucagon receptor from activation of adenylate cyclase [6]. Note that glucagon receptor antagonism may alter other physiologic effects of glucagon such as lipid metabolism, and it is possible that blocking glucagon action could activate some form of feedback to increase glucagon secretion.

As noted earlier, GLP-1 receptor agonists reduce prandial glucagon secretion. The somatostatin analogue octreotide can also suppress glucagon secretion and delay intestinal glucose absorption as well as preventing growth hormone secretion. However, octreotide also inhibits insulin secretion, precluding use in T2DM, although it is potentially useful for glycemic control with insulin in type 1 patients [6].

Glucocorticoid antagonists

Since excess glucocorticoids promote truncal obesity, insulin resistance, and hyperglycemia, tissue-specific inhibitors of glucocorticoid action have been sought to prevent metabolic effects in liver and adipose tissue without significantly interrupting other effects of these steroids. Targeting glucocorticoid receptor binding in liver, for example by conjugating glucocorticoid receptor binding inhibitors to bile salts, has reduced hyperglycemia in animal models [6].

11beta-hydroxysteroid dehydrogenase-1 (11β-HSD1) inhibitors

Cortisol is converted to inactive cortisone in the kidney by 11β-HSD2 and converted back to active cortisol by the
Figure 47.8 Cellular conversion of active cortisol to relatively inactive cortisone by 11beta-hydroxysteroid dehydrogenase-2 (11β-HSD2) in the kidney, and conversion back to active cortisol by 11beta-hydroxysteroid dehydrogenase-1 (11β-HSD1) in liver and adipose tissue.

reductase activity of 11β-HSD1 which is predominantly expressed in liver and adipose tissue (Figure 47.8). Selective inhibitors of 11β-HSD1, which reduce intracellular cortisol in liver and adipose tissue, have been shown to improve insulin sensitivity, improve glycemic control, reduce body weight, and improve the lipid profile in overweight and obese type 2 diabetes patients [45]. However, avoiding some reduction in circulating cortisol and so preventing a compensatory increase in ACTH has proved challenging. Also, possible effects of inhibiting 11β-HSD1 in islet β cells remain to be established.

Dehydroepiandrosterone (DHEA)

Administration of the adrenal androgen dehydroepiandrosterone (DHEA) and an etiocholanolone metabolite improves glycemic control, reduces insulin resistance and decreases adiposity in obese diabetic animals but this has not been duplicated in clinical studies [46].

Direct modifiers of glucose metabolism

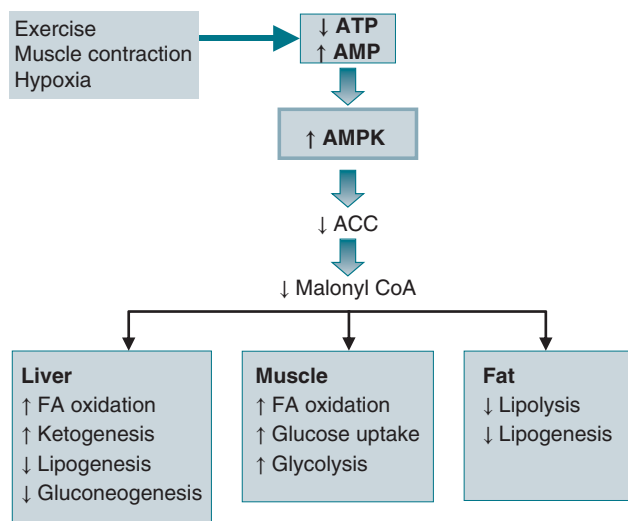
Many substances are known to exert some insulin-like effects that can lower blood glucose concentrations in diabetic animal models. However, most of these substances have other effects that preclude their consideration for long-term clinical use, for example deoxyfrenolicin, vitamin K5, spermine, diamides, and peroxides [6]. Other substances such as okadaic acid and phorbol esters initially imitate certain effects of insulin, but then prevent tissues from responding to insulin. Dichloroacetate and its esters increase glucose oxidation by stimulating pyruvate dehydrogenase, and suppress hepatic glucose production by inhibiting pyruvate carboxylase, but produce glyoxylate and oxylate which can adversely affect neural function.


Figure 47.9 Metabolic effects of the energy-regulating enzyme adenosine monophosphate-activated protein kinase (AMPK). ACC, acetyl CoA carboxylase; ↑, increase; ↓, decrease.

The antioxidant alpha-lipoic acid, used in some countries to treat diabetic neuropathy, increases insulin sensitivity and improves glucose metabolism, probably due in part to its action as a cofactor for dehydrogenases involved in glycolysis and the Krebs cycle; this has been considered as a possible adjunct to assist glycemic control but is required in high dosages.

AMP kinase activators

When the energy levels of cells become depleted, concentrations of adenosine triphosphate (ATP) and creatine phosphate (CP) decline, whereas concentrations of adenosine monophosphate (AMP) become raised. Rising AMP concentrations activate the enzyme adenosine monophosphate-activated protein kinase (AMPK) which promotes energy production by increasing the uptake and oxidation of glucose and fatty acids to replenish ATP (Figure 47.9). AMPK also reduces expression of phosphoenolpyruvate carboxykinase (PEPCK) — a key enzyme for gluconeogenesis, and may suppress cell proliferation. Metformin, thiazolidinediones and adiponectin activate AMPK amongst other actions that contribute to their glucose-lowering effects [47]. Since analogues of AMP such as 5-aminoimidazole-4-carboxamide-1-B-D-ribofuranoside (AICAR) activate AMPK and improve glycemic control in insulin-resistant diabetic animals, further activators of AMPK are under investigation as potential diabetes therapies.

Glycogen synthase kinase inhibitors

Glycogen synthesis is impaired in T2DM, due in part to reduced activity of glycogen synthase. Glycogen synthase is normally deactivated by the enzyme glycogen synthase kinase-3 (GSK3), whereas glycogen synthesis proceeds when GSK3 is inactivated by insulin via the PI3K-Akt pathway. Since GSK3 activity is increased in insulin-resistant diabetic states, small molecule inhibitors of GSK3 have been developed which have increased insulin-stimulated glycogenesis and lowered blood glucose in insulin-resistant diabetic animals. However, GSK3 has diverse signaling roles affecting neuronal metabolism, protein degradation and apoptosis which present difficulties for specifically targeting glycogen metabolism [6].

Inhibitors of hepatic glucose production

Various interventions have been investigated to suppress hepatic gluconeogenesis and/or glycogenolysis. These need to be reversed rapidly if blood glucose concentrations fall below the normal range so that counterregulatory responses can operate to avoid hypoglycemia [48]. Inhibitors of glycogen phosphorylase have shown glucose-lowering efficacy in diabetic animal models, but there is limited clinical evidence as yet. Glucose-6-phosphatase inhibitors reduce hepatic glucose output and lower blood glucose by preventing the last step in glucose output from both glycogenolysis and gluconeogenesis. However, there is a high risk of hypoglycemia, and cellular accumulation of glucose-6-phosphate increases glycogen deposition and lipogenesis which predispose to fatty liver. The step in gluconeogenesis before glucose-6-phosphate is the formation of fructose-6-phosphate from fructose-1,6-bisphosphate, mediated by fructose-1,6-bisphosphatase (F16BPase). Inhibitors of F16BPase reduce hepatic glucose output and may cause a compensatory increase in glycogenolysis which could help to guard against hypoglycemia.

Modifiers of lipid metabolism

Dyslipidemia in T2DM typically involves raised concentrations of very low-density lipoprotein (VLDL) triglyceride and nonesterified fatty acids (NEFAs) which contribute to insulin resistance and hyperglycemia [21]. Raised concentrations of fatty acids and their metabolites impair cellular insulin signaling pathways and alter fuel selection through the glucose–fatty acid (Randle) cycle. Thiazolidinedione PPARγ agonists act in part by altering fatty acid metabolism, and lipid-lowering fibrates, which are PPARα agonists, may improve glycemic control in some patients. Other agents that lower plasma triglycerides or NEFA concentrations have been shown to acutely improve glycemic control in T2DM, but effects have not been consistent and often not sustained [6].

Inhibiting fatty acid oxidation interrupts the energy supply for hepatic gluconeogenesis and enhances the use of glucose as a source of energy in skeletal muscle. Most inhibitors of fatty acid oxidation act by inhibiting carnitine palmitoyltransferase-1 (CPT-1), the rate-limiting enzyme for transfer of long-chain fatty acyl-CoA into the mitochondria. These have effectively lowered glucose concentrations but carry a high risk of hypoglycemia [6].

Sodium-glucose co-transporter inhibitors

The sodium-glucose co-transporter-2 (SGLT2), located almost exclusively in the proximal convoluted tubules, is a high capacity co-transporter responsible for reabsorption of most of the glucose filtered by the renal glomeruli. Partial competitive reversible inhibition of this co-transporter reduces glucose reabsorption, enabling excess glucose to be eliminated in the urine (Figure 47.10). The mechanism is independent of insulin, allowing inhibitors of SGLT2 to be used alone or in combination with other therapies to reduce hyperglycemia at different stages in the natural history of T2DM, provided there is adequate renal function [49]. The extra glucosuria typically accounts for 50–90 g glucose cleared daily (equating 200–360 kcal) depending on the extent of the hyperglycemia and renal function. Thus, in addition to reducing hyperglycemia, SGLT2 inhibitors can assist body weight reduction. Since SGLT2 inhibition does not stimulate insulin secretion or interrupt the counterregulatory system, there is low risk of hypoglycemia unless used with agents that carry their own inherent risk of hypoglycemia. While glucosuria increases the risk of urinary and genital infections, the osmotic diuresis generated by the glucosuria may benefit blood pressure control as seen with a mild diuretic. Four members of the SGLT2 inhibitor class (dapagliflozin, canagliflozin, empagliflozin, and ipragliflozin) have recently been introduced.

SGLT1 is a low-capacity co-transporter also located within the proximal tubules but distally to SGLT2. SGLT1 can reabsorb small amounts of glucose that evade reabsorption by SGLT2, and blockade of SGLT1 can support the glucosuric effect. SGLT1 is also the co-transporter for glucose absorption by the small intestine, and its inhibition can delay and slow glucose absorption. Hence agents with inhibitory effects on SGLT2 and SGLT1 are in development with pharmacokinetic properties selected to avoid malabsorption and passage of glucose into the large bowel. It is also noted that renal reabsorption of low glucose concentrations by SGLT1 may help to provide a buffer against the risk of hypoglycemia.

Sirtuins

Sirtuin enzymes are nicotinamide-adenine-dinucleotide (NAD)-dependent deacetylases and/or ADP-ribosyltransferases. Their effects include altering gene transcription through chromatin silencing, and they mediate metabolic responses that
Figure 47.10 Renal sodium-glucose co-transporters reabsorb glucose from the proximal convoluted tubule (PCT). Glucose is filtered at the glomerulus into the PCT and mostly resorbed in the initial region of the PCT by the high-capacity low-affinity sodium-glucose co-transporter-2 (SGLT2). Remaining glucose is reabsorbed more distally along the PCT by low-capacity high-affinity sodium-glucose co-transporter-1 (SGLT1).

resemble chronic caloric restriction. Sirtuin sirt1 is widely expressed in mammalian tissues including liver, muscle and fat, and promotes mitochondrial biogenesis, increasing thermogenesis and reducing susceptibility to weight gain, diabetes, and cardiovascular disease. AMPK enhances sirt1 activity, resulting in increased activity of downstream transcription factors such as PGC-1α and the forkhead protein FOXO1 which increase energy production. Sirt1 in pancreatic β cells may also facilitate insulin secretion. Several small molecule activators of sirt1 such as the phytophenol resveratrol have been shown to increase mitochondrial density, and improve insulin sensitivity, glycemic control, and eNOS-dependent vasorelaxation in animal models, providing a template for other activators of sirt1 [50].

Conclusions

The multivariable etiology, pathogenesis, progression and morbidities of T2DM require the development of a variety of different treatments that can be used to address the different adverse features of the disease as it advances. There are new types of agents at various stages of development to improve the function of the pancreatic islets, enhance insulin action, reduce glucose production, facilitate glucose metabolism, or reduce the impact of internal factors that act counter to the reinstatement of normal glucose homeostasis. Despite the many initiatives under investigation there is still an evident paucity of prospective interventions to prevent or reverse the loss of functional β-cell capacity and responsiveness, and a need for additional measures to address the diverse consequences of insulin resistance.

Incretin-based therapies

Michael A. Nauck[1] and Juris J. Meier[2]

[1]Diabeteszentrum Bad Lauterberg, Bad Lauterberg im Harz, Germany

[2]Division of Diabetes and Gastrointestinal Endocrinology, University Hospital St. Josef-Hospital, Ruhr-University Bochum, Gudrunstr, Bochum, Germany

Key points

- Incretin-based medications make use of the glucose-lowering activity of the gut incretin hormone glucagon-like peptide-1 (GLP-1), which stimulates glucose-dependent insulin secretion, suppresses glucagon secretion, decelerates gastric emptying, reduces appetite and food intake, and may have other actions in the nervous and cardiovascular systems.

- Incretin mimetics (GLP-1 receptor agonists) are peptides that need to be injected subcutaneously (such as insulin) and have a much longer half-life than native GLP-1, so can be injected at intervals between twice daily (exenatide, unretarded), once daily (liraglutide), or once weekly (exenatide once weekly, and novel compounds currently under development).

- DPP-4 inhibitors preserve GLP-1 secreted from endogenous sources in its intact, biologically active state, so that for the same amount released from the intestines more GLP-1 receptor stimulation takes place, thereby increasing insulin secretion relative to ambient levels of glycemia, and suppressing glucagon secretion.

- Incretin-based medications have the advantage of not causing hypoglycemic episodes due to their glucose-dependent mechanism of action on insulin and glucagon secretion. Nevertheless, hypoglycemia can be caused by concomitant medications (insulin, sulfonylureas) and this risk is increased by incretin-based antidiabetic medications because of their glucose-lowering activity.

- Incretin mimetics induce some weight loss in the average patient, but there is marked heterogeneity between patients regarding their susceptibility towards weight loss induced by GLP-1 receptor stimulation. Nevertheless, this is attractive for patients who have unsuccessfully tried to lose weight on medications that tend to increase body weight, such as sulfonylureas, meglitinides, thiazolidinediones, or insulin.

Biologic actions of incretin hormones in patients with type 2 diabetes mellitus

Incretin hormones are gut peptides released after nutrient ingestion which have the ability to augment insulin secretory responses, provided there is a permissive rise in glycemia, as is typical after meals. The two well-defined incretin hormones are glucose-dependent insulinotropic polypeptide (formerly called gastric inhibitory polypeptide; GIP) and glucagon-like peptide-1 (GLP-1). Their physiologic role is best exemplified by looking at the difference in insulin secretory responses after an oral glucose challenge in healthy subjects compared to an "isoglycemic" intravenous (i.v.) glucose infusion, which provides an identical rise in glycemia (i.e., an identical glycemic stimulus to the endocrine pancreas). Nevertheless, much more insulin (and C-peptide) is released in response to the oral stimulus, which leads to the release (from the gut) and insulinotropic action (on the endocrine pancreas) of the incretin hormones. This phenomenon is called the incretin effect and is responsible for two-thirds of insulin secretory response following a standard (75 g) oral glucose challenge. For more details on the physiology and pathophysiology of the incretin system, see Chapter 11 on incretin physiology in health and disease. GIP was discovered earlier, probably contributes most of the incretin effect in healthy human subjects, but is inactive as an insulinotropic agent in patients with T2DM, because type 2 diabetic β cells show very weak responses to GIP only. This explains why patients with T2DM have a reduced or even absent incretin effect. GLP-1 probably makes a minor physiologic contribution to the incretin effect (among other reasons, because gastric emptying is delayed, preventing a permissive glycemic rise), but retains much of its insulinotropic activity in T2DM. Thus, it has been possible to elicit an insulin secretory response to exogenous GLP-1 at low pharmacologic concentrations in patients with T2DM, and it has also been possible to normalize fasting glucose in hyperglycemic patients with T2DM. Such proof-of-principle experiments demonstrate the therapeutic potential of GLP-1 receptor stimulation to lower glucose in these patients. On the other hand, GLP-1 is rapidly degraded and inactivated by dipeptidyl peptidase-4 (DPP-4), a ubiquitous protease, and in addition, is rapidly eliminated via the kidneys,

such that the half-life of intact, biologically active GLP-1 (7-36 amide) is only approximately 1.5 min [1,2].

GLP-1 as a parent compound for incretin-based antidiabetic drugs

1 GLP-1 can augment glucose-induced insulin secretion in healthy subjects and in patients with T2DM.
2 GLP-1 suppresses glucagon secretion at glucose concentrations ranging from the normal fasting range to hyperglycemia. At hypoglycemic blood glucose concentrations, when glucagon is needed as an important counterregulatory hormone, GLP-1 no longer suppresses glucagon secretion — the counterregulatory response remains normal even in the face of high, pharmacologic concentrations of GLP-1.
3 GLP-1 delays gastric emptying. This leads to a slower entry of nutrients into the circulation, and smaller rises in glucose and triglyceride concentrations after meals.
4 GLP-1 in the general circulation has access to brain areas involved in the regulation of satiety, appetite, food intake, and energy expenditure. GLP-1 increases satiety and the feeling of fullness, reduces appetite and the desire to eat, and decreases food (energy) intake. These are the prerequisites for weight loss in the longer term. These actions match the typical therapeutic challenges in patients with T2DM, namely,
   ∘ defective insulin secretion due to a reduced mass and function of β cells;
   ∘ hyperglucagonemia leading to exaggerated hepatic glucose output in the fasting state and after meals;
   ∘ exaggerated hyperglycemia after eating; and
   ∘ obesity [2].

In addition to these core biologic activities, the following biologic activities have been described:
1 Improvements in (pro-)insulin biosynthesis, induction of neogenesis and/or proliferation of β cells, and prevention of apoptosis induced by a variety of toxic factors (hydrogen peroxide, cytokines, and so on). Most of these experiments have been performed in young rodents and cell lines. It has not been as easy to demonstrate similar findings in older animals. It is an open question whether such β-cell-preserving effects apply to patients with T2DM treated with incretin-based medications;
2 Neuroprotective actions in the (central) nervous system;
3 Cardiovascular actions at the level of the endothelium, leading to vasodilatation, and at the level of the ischemic or failing heart, leading to reduced myocardial necrosis in the case of induced myocardial ischemia, and increased oxygen and glucose uptake and utilization and improved left ventricular function in the case of congestive heart failure [2].

Development of GLP-1 receptor agonists (incretin mimetics)

For therapeutic purposes, compounds with the ability to activate GLP-1 receptors, but with a much longer half-life than the parent compound GLP-1 were needed. Ideally, such compounds should be resistant to proteolytic degradation and inactivation by DPP-4. Two approaches were taken: (i) natural compounds with GLP-1 receptor agonistic properties were sought, and (ii) GLP-1 was intentionally modified with the aim of preserving a high degree of homology with the parent compound, but prolonging the half-life to allow for reasonable inter-injection intervals [2].

Exeantide

Exenatide (Byetta®) is synthetic exendin-4, a peptide identified in the saliva from *Heloderma suspectum* (the "Gila monster"), a lizard from Arizona. Similarities in the amino acid sequence to GLP-1 prompted examinations demonstrating exenatide to be a potent GLP-1 receptor agonist. Exenatide is a longer peptide molecule than GLP-1, and displays approximately 53% sequence homology. Pharmacokinetic examinations in human subjects indicate a half-life of approximately 2–3 hours. After a single subcutaneous injection, plasma levels peak after 2 h and remain elevated for 6–7 h [3]. A phase 2 study indicated that three injections before the main meals were no more efficient at reducing HbA1c than two injections before breakfast and dinner. Almost all studies since have employed two injections per day. The injection should be timed within 60 min before ingesting the respective meal. Fifteen minutes prior to eating is a reasonable recommendation. Exenatide is administered using a pen device. Pens are available that deliver 5 or 10 μg per dose. The recommended starting dose is 5 μg twice daily. After 4 weeks (when exenatide from the first pen has been used up), patients can change to another pen that delivers 10 μg per dose. The maintenance dose for most patients is 10 μg twice daily, unless adverse events suggest continuing at the lower dose because it is better tolerated, or in cases of moderate renal functional impairment (eGFR 30–50 mL min^{-1}), making a dose reduction necessary.

Liraglutide

Liraglutide (Victoza®) was the first "designer molecule" developed as a GLP-1 receptor agonist. The core peptide has only been slightly modified (in comparison to GLP-1 (7-36 amide), the homology being 97%). A lysine residue in amino acid position 34 had to be changed to an arginine residue, because a side chain with a free fatty acid (FFA) moiety was to be attached to another lysine residue in a selective manner. This FFA side chain (similar to insulin detemir) mediates binding to albumin, the noncovalent liraglutide-albumin conjugate forming a reservoir, from which liraglutide can be liberated to diffuse into tissues and bind to receptors. Although the amino acids at the amino-terminus have not been changed relative to the native GLP-1 peptide, DPP-4 hardly attacks liraglutide, most likely because the FFA side chain can cause steric hindrance. The half-life of liraglutide is approximately 13 hours. With one subcutaneous injection, plasma concentrations remain elevated after 24 h, and with repeated, once-daily subcutaneous injections, a steady state of plasma concentrations is reached after approximately 5 days [4]. Within a 24-h period,

plasma concentrations then fluctuate by approximately 25%. Thus, liraglutide concentrations are permanently elevated with once-daily injections, including the overnight period, where stimulation of insulin secretion and suppression of glucagon secretion lead to a substantial reduction in fasting plasma glucose. Such a prominent effect on fasting plasma glucose is not seen with shorter-acting GLP-1 receptor agonists such as exenatide and lixisenatide. Liraglutide injections do not need to be timed with meals. Patients should choose a time point during the day when they can most conveniently deliver the liraglutide injection every day (± 1 h). Liraglutide therapy is started at a subcutaneous dose of $0.6\,\mathrm{mg\,d^{-1}}$. After one week the dose can be raised to $1.2\,\mathrm{mg\,d^{-1}}$. There is an option to further increase the dose to $1.8\,\mathrm{mg\,d^{-1}}$ but stepping up the dose from 1.2 to $1.8\,\mathrm{mg\,d^{-1}}$ is not expected to greatly improve glycemic control [5]. However, slightly more weight loss may be expected at the higher dose. In fact, weight loss trials in nondiabetic obese subjects have utilized up to $3.0\,\mathrm{mg}$ liraglutide per day, improving weight loss over lower doses.

Exenatide once weekly

Exenatide is now available in a new preparation (Bydureon®) developed for slow and prolonged release from microspheres that encapsulate the compound in a polymer that slowly dissolves in the subcutaneous tissue and releases the peptide. Exenatide once weekly is available only at one dose, 2 mg. For subcutaneous injections, exenatide powder needs to be re-suspended in a single-use device. Since this suspension is more viscous than an aqueous solution, an 8 mm 23-gauge needle is used as part of this package. With once-weekly subcutaneous injections, it takes 6–10 weeks before a steady state of concentrations is reached [6], which thereafter is maintained with once-weekly injections. After discontinuing treatment, it takes several weeks before all previously injected exenatide is absorbed and eliminated.

Agents under development

Albiglutide is composed of two molecules of modified GLP-1 attached to one molecule of human albumin. Despite the much larger molecular size (compared to GLP-1, exenatide, and liraglutide), albiglutide is able to stimulate the GLP-1 receptor. However, because of the greater molecular size, the molecule may not fully access the central nervous system. Albiglutide has a half-life of approximately 5 days in humans and needs to be injected once weekly. Attempts to prolong the interval between injections to 2 or even 4 weeks led to fluctuations in glycemic control throughout the inter-injection interval, probably prompted by fluctuations in plasma concentrations of albiglutide. Albiglutide has not yet been approved. Most likely, once-weekly doses of 30 mg (for an initial treatment of 6 weeks) and 50 mg (for maintenance treatment) will be used [7].

Lixisenatide is a derivative of exenatide, which has so far not been approved for the treatment of T2DM. It has a similar short action to exenatide, but lixisenatide has been developed for once-daily subcutaneous dosing [7]. Thus, it has limited ability to lower fasting glucose in hyperglycemic patients, but like exenatide, it can profoundly affect postprandial glycemic excursions through its ability to retard gastric emptying even with long-term use. With these properties, it is likely to be used mainly as an adjunct to insulin therapy.

Dulaglutide is a fusion molecule of GLP-1 and an immunoglobulin Fc fragment. It is being developed for administration once weekly [8]. Protracted effects of PEGylated GLP-1 have been described in preclinical studies.

Small molecules activating the GLP-1 receptor have been found that may prove that oral agents can be developed in addition to the GLP-1-agonistic peptides that are currently used as incretin mimetics.

Efficacy of incretin mimetics as glucose-lowering agents (reduction in HbA1c)

For diabetes medications, the key feature of incretin mimetics is their ability to lower/control glucose, a prime factor in preventing long-term complications induced by long-standing hyperglycemia.

Monotherapy

Exenatide at $10\,\mu\mathrm{g}$ twice a day is able to reduce HbA1c by 0.9 % (0.2% with placebo) in patients with T2DM not concomitantly treated with other (oral) glucose-lowering agents [9]. Liraglutide has been proven to lower HbA1c by 1.1% in monotherapy [10]. Exenatide once weekly has been studied in populations including patients with T2DM not previously or concomitantly treated with other glucose-lowering agents. The results for these subpopulations have not been reported separately. The main use of GLP-1 receptor agonists is as add-on to oral glucose-lowering therapy, since guidelines uniformly recommend metformin as the first choice for initial drug therapy. However, exenatide (unretarded), liraglutide, and exenatide once weekly can be used in drug-naïve patients in monotherapy, if metformin and other agents are contraindicated or cannot be tolerated.

Add-on to oral glucose-lowering agents

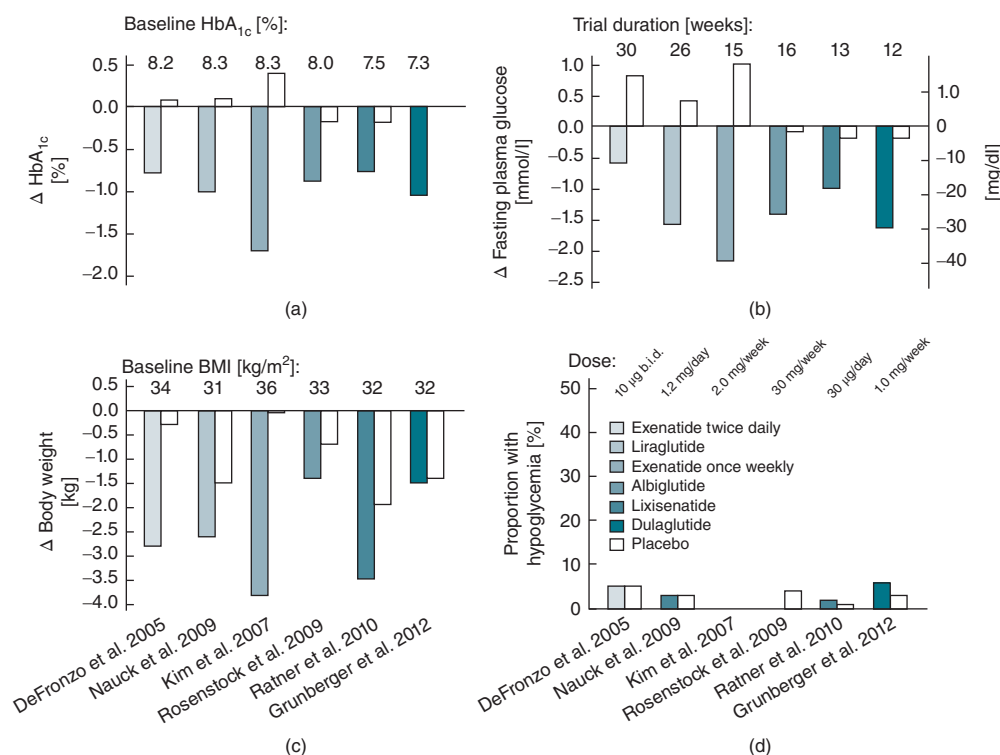
For injectable agents like GLP-1 receptor agonists, the logical place in the treatment algorithm is as add-on to oral antidiabetic agents as an alternative to insulin treatment, or to other oral glucose-lowering drugs in cases where these agents cause adverse effects. Exenatide (unretarded), liraglutide, and exenatide once weekly have been studied against a background of metformin, sulfonylureas, a combination of metformin and sulfonylureas, thiazolidinediones, and a combination of metformin and thiazolidinediones. In many studies, mixed populations encompassing, for example, drug-naïve patients, metformin-treated patients, and patients treated with a combination of metformin and sulfonylureas, have


Figure 48.1 Essential results from clinical trials with different GLP-1 receptor agonists compared to placebo treatment, both administered on a metformin background. Effect on HbA1c (a), fasting plasma glucose (b), body weight (all Δ versus baseline) and proportion of patients reporting at least one episode of hypoglycemia (d). Trials can be identified by first author and year of publication. Baseline HbA1c (a), trial duration (b), baseline BMI (body mass index) (c), and dose as well as the typical interval between two injections (d) are also indicated. For references, see [5,7,8,23,49,50].

been examined without reporting the treatment results in subgroups. Generally speaking, the ability of GLP-1 receptor agonists to control glycemia does not depend to a great extent on background treatment with oral glucose-lowering agents (Figure 48.1).

Head-to-head studies comparing incretin mimetics have shown important differences: long-acting agents (i.e., those that lead to a constantly elevated plasma drug concentration throughout the 24-h period, such as liraglutide and exenatide once weekly), show lower overnight and fasting glucose concentrations, resulting in a greater reduction in HbA1c; whereas with short-acting agents, peak-to-trough levels are observed between injections (unretarded exenatide, lixisenatide). Short-acting agents exert only limited effects on fasting glucose, because with the typical injection regimen, overnight drug levels are low. Thus, unretarded exenatide has been shown to be less effective in controlling HbA1c than liraglutide [11] or exenatide once weekly [6].

Liraglutide at 1.8 mg d^{-1} has also been compared to exenatide once weekly (2 mg per week) and albiglutide (30 mg once weekly followed by 50 mg once weekly after week 6). In both comparisons, liraglutide treatment was associated with a superior reduction in HbA1c [12,13], although the difference was a mere 0.2–0.3 % and thus of negligible or questionable clinical relevance. Nevertheless, liraglutide at a once-daily injection

regimen appears to be the most potent GLP-1 receptor agonist currently available for the treatment of T2DM. Explanations for this may be:

1 that the trials were too short for the longer acting incretin mimetic to catch up with the more pronounced initial effectiveness of liraglutide, which reaches a steady state after approximately 5 days rather than several weeks;

2 only single doses of each agent were compared, and the dose–response relationships have not been characterized to the degree necessary to unequivocally define optimum doses for each GLP-1 receptor agonist. Thus, conclusions cannot be drawn that any agent is more effective than another compound, and should be limited to the doses employed in the clinical trials;

3 the possibility cannot be excluded that larger inter-injection intervals lead to fluctuations in drug levels and associated effects between two injections, with weaker effects at times characterized by relatively lower drug concentrations.

Comparison to insulin treatment

For all available GLP-1 receptor agonists, clinical trials have been carried out to compare their glycemic control effects with those of insulin regimens. Exenatide (unretarded) has been compared to both premixed insulin [14,15] and the long-acting insulin analogue insulin glargine; liraglutide [16] and exenatide once

weekly [17] have been compared to insulin glargine. In all comparisons, the incretin mimetic was at least as effective in lowering HbA1c as the insulin regimen. In some trials, the insulin preparation was more effective at reducing fasting glucose, suggesting a greater postprandial mode of action by the incretin mimetic, but this was not the case when comparing liraglutide with insulin glargine [16]. Since all GLP-1 receptor agonists are used in a standard dose, while insulin always needs to be titrated, the question arose whether weaknesses (inertia) in the titration process might explain the relatively good performance of the incretin mimetics. Some of the studies achieved average insulin doses similar to those in treat-to-target trials, contradicting this assumption. Most likely, in clinical practice, similar limitations apply to the titration process of insulin. Thus, GLP-1 receptor agonists are similarly potent as insulin in helping patients with T2DM to achieve their HbA1c targets (Figure 48.2).

Combination with basal insulin

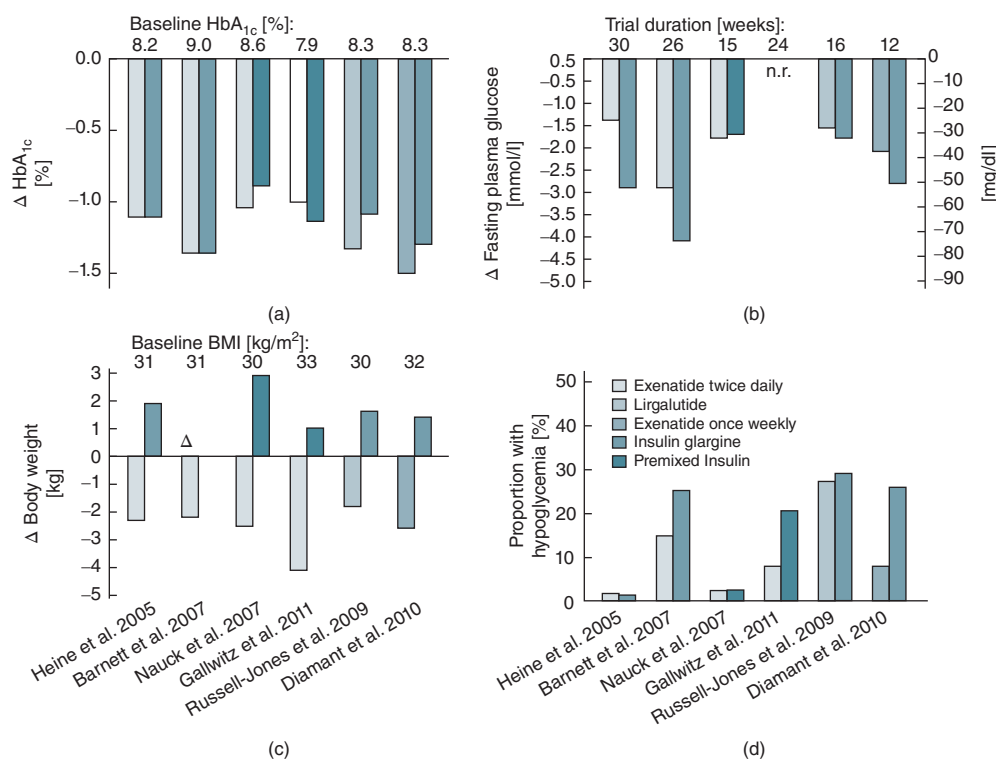
Short-acting GLP-1 receptor agonists considerably decelerate gastric emptying even with long-term use [18]. Therefore, it is probably not wise to combine them with rapid-acting insulin injected before meals, because this combination is likely to provoke hypoglycemia as the insulin will peak before the nutrients enter the circulation. However, one prominent "weakness" of short-acting incretin mimetics is their relatively minor effect on fasting glucose, while their obvious strength is the control of postprandial glycemic rises, mostly mediated by the retardation in gastric emptying which persists with continued use of exenatide and lixisenatide. On the other hand, regimens that rely on long-acting insulin (mostly in combination with oral antidiabetic agents, preferably metformin) can control fasting glycemia very well, but are often associated with relatively large postprandial glycemic increments. Thus, a combination of a long-acting insulin such as insulin glargine or insulin detemir with a short-acting incretin mimetic like exenatide or lixisenatide can provide good glycemic control in the fasting and postprandial state. Comparative trials to intensified insulin regimens (multiple daily injections) are not available, but insulin glargine in combination with exenatide (unretarded) leads to weight loss, and the addition of exenatide to insulin glargine did not increase the number or severity of hypoglycemic episodes [19]. Benefits of combining liraglutide with insulin detemir have also been reported [20]. This combination may be among the most efficient regimens to treat long-standing T2DM in patients in whom other regimens are more likely to fail.


Figure 48.2 Essential results from clinical trials with different GLP-1 receptor agonists compared to insulin treatment, both administered on a background of oral antidiabetic agents. Effect on HbA1c (a), fasting plasma glucose (b), body weight (all Δ versus baseline) and proportion of patients reporting at least one episode of hypoglycemia (d). Trials can be identified by first author and year of publication. Baseline HbA1c (a), trial duration (b), baseline BMI (body mass index) (c), and dose as well as the typical interval between two injections (d) are also indicated. N.r., not reported; Δ, the bar indicates the difference between insulin and exenatide treatment. For references, see [14–17,51,52].

Inability to provoke hypoglycemia

GLP-1 even in high doses and GLP-1 receptor agonists at low glucose concentrations cannot elicit insulin secretory responses or other glucoregulatory activities potent enough to cause hypoglycemia. The reason is the inability of GLP-1 receptor stimulation to close ATP-dependent potassium channels in β cells, a step necessary to initiate insulin release. In line with this physiologic explanation, hypoglycemia rates in clinical trials involving incretin mimetics have always been low, at similar levels to placebo or metformin. Severe episodes of hypoglycemia have been observed extremely rarely under such conditions, most trials reporting no such episodes. This changes, however, as soon as incretin mimetics are combined with other drugs which have the potential to induce hypoglycemia, namely sulfonylureas, meglitinides (which have the potential to close ATP-dependent potassium channels at any ambient level of glycemia), or insulin. Under such circumstances, the rate of hypoglycemia usually increases with treatment using incretin mimetics, because of their additional glucose-lowering effect. Since providing glycemic control with a low or absent risk for hypoglyemic episodes is an important goal, potential benefits need to be weighed against the potential to provoke hypoglycemia before combining incretin mimetics with sulfonylureas or meglitinides. The addition of short-acting incretin mimetics to treatment with long-acting insulin does not seem to increase the risk of hypoglycemia substantially [2].

Deceleration of gastric emptying

GLP-1 and GLP-1 receptor agonists decelerate gastric emptying through a mechanism involving the parasympathetic nervous system (afferent and efferent vagus branches). Acutely, GLP-1 at doses that do not cause gastrointestinal side effects, can lead to a standstill of gastric emptying. Lower doses just retard gastric emptying, by interrupting the transpyloric delivery of nutrients, thus delaying the absorption of nutrients and their entry into the circulation. This is the main reason that incretin mimetics profoundly limit postprandial glycemic rises in glucose, and also in triglyceride concentrations. It is likely that all incretin mimetics delay gastric emptying on first exposure [21]. With prolonged treatment (i.e., after days to weeks), there appears to be tachyphylaxis regarding the ability to delay gastric emptying with long-acting GLP-1 receptor agonists, because the typical dosing regimen leads to permanently elevated plasma concentrations of the compound with no nadirs close to zero concentrations. This description is true for liraglutide, exenatide once weekly, and albiglutide. Only short-acting incretin mimetics like exenatide (unretarded) and lixisenatide preserve their ability to retard gastric emptying with prolonged treatment, because the exposure to the agent is intermittent, with low drug levels close to zero concentrations in between injections, which are apparently necessary to maintain the full responsiveness to this action following GLP-1 receptor stimulation [22]. It is important to mention that other activities induced by GLP-1 receptor stimulation are not subject to tachyphylaxis. This applies to the stimulation of insulin secretion, the suppression of glucagon secretion, and the reduction in appetite and food intake. The only other example of reduced effectiveness with prolonged exposure to GLP-1 receptor agonists is the reduced probability of gastrointestinal adverse events with longer treatment duration.

Inducing weight loss

Incretin mimetics, on average, induce some weight loss. This weight loss is in the order of 2–4 kg for the average patient, and appears to be maintained as long as GLP-1 receptor agonist treatment is continued. At the individual patient level, the weight response is heterogeneous, with some patients losing more than 10 kg, while others do not lose weight at all or may even gain some weight. What determines the individual responses is not known. Generally speaking, weight loss, even if it is moderate for most patients, is an attractive component of the spectrum of clinical effects induced by treatment with incretin mimetics, considering that other antidiabetic medications like sulfonylureas, meglitinides, thiazolidinediones, and insulin typically cause patients to gain body weight.

The signaling pathway that leads to a reduction in appetite and food intake when patients are treated with incretin mimetics involves central nervous system areas in the hypothalamus responsible for the regulation of energy intake and expenditure. Whether GLP-1 receptor agonists cross the blood–brain barrier or interact with receptors in parts of the central nervous system that are devoid of a blood–brain barrier ("subfornical organs"), or whether the primary interaction is with GLP-1 receptors on afferent parasympathetic (vagal) branches is not known [2].

Theoretically, reduced food intake could also be due to the fact that incretin mimetics retard gastric emptying. It is obvious that if the stomach is still partially filled from a previous meal, this could lead to reduced appetite and food intake. However, although theoretically this sounds plausible, no direct evidence has been provided that this mechanism is active and contributes to weight loss during treatment with GLP-1 receptor agonists.

Short-acting (e.g. exenatide, unretarded) and long-acting (e.g. liraglutide, exenatide once weekly) GLP-1 receptor agonists appear to have a similar potential to induce weight loss, based on head-to-head comparisons between these agents. Since treatment with short-acting incretin mimetics is characterized by a persistent deceleration of gastric emptying, even with long-term treatment, whereas long-acting GLP-1 receptor agonists lose this activity through tachyphylaxis, this speaks against a major contribution of delayed gastric emptying to weight loss. Alternatively, other mechanisms may compensate for the varying contribution of delayed gastric emptying.

In head-to-head comparisons of liraglutide with exenatide once weekly [11] and with albiglutide [13], weight loss was

more pronounced with liraglutide than with the once-weekly preparations. This could be the consequence of an overall lesser effect, perhaps related to the doses used in these particular studies. In the case of albiglutide, the difference was substantial and raises the question whether the ability of albiglutide to trigger the mechanisms leading to weight loss is reduced in comparison with other incretin mimetics, possibly related to its larger molecular size, which could be responsible for reduced access to the central nervous system.

The potential to induce weight loss is an important factor driving the prescription of incretin mimetics. Whereas the use of antidiabetic medications that promote weight gain often leads to demotivation amongst patients whose efforts to adopt a healthy lifestyle, including avoidance of excess caloric intake, are unsuccessful, supporting weight reduction pharmacologically hopefully will motivate patients to eat healthy amounts of food for prolonged periods of time. Nevertheless, the effects of patient education supporting healthy eating in connection with the initiation of treatment with incretin mimetics have not received the emphasis that they probably deserve. Most likely, patients could be trained to become sensitive, with the help of GLP-1 receptor agonists, to the signals that should make them stop eating, once satiety and fullness have reached a certain level after meals.

Gastrointestinal adverse events

GLP-1 and all GLP-1 receptor agonists can cause nausea, vomiting, diarrhea and other gastrointestinal adverse events. Such side effects are thought to be dose-related. Often, they are thought to be mediated by the well-known deceleration of gastric emptying, in the sense that in the absence of propulsive movement of gastric contents, distension and symptoms will be the consequence. More likely, these adverse events are mediated by a direct interaction of GLP-1 and the GLP-1 receptor agonist with target areas of the central nervous system, and thus, can occur in fasting subjects and after food intake.

Uniformly, with all GLP-1 receptor agonists, two phenomena have been observed. (1) The percentage of patients affected by nausea, vomiting, and/or diarrhea will be highest upon initial exposure, gradually declining over days or weeks, until just a small percentage of patients remain, in whom persistent gastrointestinal side effects are observed [5,6,23,24]. Some patients will not tolerate this and will discontinue treatment with GLP-1 receptor agonists. This applies to approximately 3–5% of the type 2 diabetic population. (2) If the dosing schedule is such that the initial exposure to the GLP-1 receptor agonist is lower, and then is gradually increased over time, higher doses can be tolerated in the long term. Therefore, exenatide (unretarded) treatment is usually initiated at $5\,\mu g$ per dose and later increased to $10\,\mu g$ per dose. Liraglutide treatment is usually initiated at $0.6\,\mathrm{mg\,d^{-1}}$ and, after one week, increased to $1.2\,\mathrm{mg\,d^{-1}}$ (perhaps later followed by a further increase to $1.8\,\mathrm{mg\,d^{-1}}$). With exenatide once weekly, even when starting the injections at the full dose (2 mg per week), the slow

absorption and elimination take care of a slowly rising plasma concentration of the agent.

In head-to-head comparisons of different GLP-1 receptor agonists, the incidence of nausea, vomiting, and/or diarrhea can differ between the compounds. As a rule, long-acting GLP-1 receptor agonists providing permanent exposure to elevated drug levels will produce less gastrointestinal side effects, especially during long-term treatment [6,11]. Certainly, the prevalence of such side effects will be reduced over time, unlike the more persistent levels found with short-acting GLP-1 receptor agonists (characterized by a rapid alternation of periods with high and low drug levels). More specifically, exenatide (unretarded) and liraglutide produce similar levels of gastrointestinal side effects initially, but with liraglutide, these levels decline over time. Exenatide once weekly and albiglutide produced less gastrointestinal side effects than did liraglutide, but they were also less effective in these trials with respect to glycemic control and weight loss, so the doses used for each agent may not have been absolutely equivalent. Differences regarding the access to the relevant brain areas may also play a role.

Antibody formation

All GLP-1 receptor agonists available for the treatment of T2DM are peptides, which typically are administered by subcutaneous injection. As with other peptides (e.g. insulin), even when they are identical or similar to those that are endogenously produced, repeated injection into the subcutaneous compartment can lead to antibody formation by the immune system. Such antibodies can reach different titres (i.e., amounts of antibodies produced) and different affinities (i.e., avidity, with which the antigen is bound), and may or may not bind the peptide in a manner that neutralizes its biologic activity. Generally speaking, the likelihood of prompting an antibody response should depend on the homology of the GLP-1 receptor agonist with endogenously produced peptides, in this case GLP-1. Exenatide has 53% amino acid sequence homology to GLP-1. With exenatide (unretarded), approximately 45% of patients develop antibodies [11]. This number increases to 60–75% with the extended-release preparation (exenatide once weekly) [6]. A few percent develop high-titre antibodies, and there is suggestive evidence that in those with high-titre antibodies, there is less clinical effectiveness of exenatide treatment [6]. Liraglutide has 97% amino acid sequence homology with GLP-1. Up to 8% of liraglutide-treated patients develop antibodies, so far without a hint that the clinical effectiveness of this treatment might be compromised by antibody formation [25].

Development of inhibitors of dipeptidyl peptidase-4 (DPP-4)

GLP-1 (like the partner incretin hormone, glucose-dependent insulinotropic polypeptide; GIP) is rapidly degraded by the

Incretin-based therapies **733**

ubiquitous endopeptidase dipeptidyl peptidase-4 (DPP-4). The original observation after the development of specific assays that enabled measurement of intact and biologically active GLP-1, was that even with a constant intravenous infusion of GLP-1 in patients with T2DM, only one sixth of the GLP-1 concentration would remain in the intact state, while the majority had already been degraded. This proved (a) the rapidity and (b) the effectiveness of the interaction between GLP-1 and DPP-4, and suggested that interference with DPP-4 activity (inhibition) might preserve endogenously produced GLP-1 in the intact and biologically active form, thus prompting a glucose-lowering effect of DPP-4 inhibitor treatment. Indeed, studies delineating the mode-of-action of DPP-4 inhibitors show the inhibition of DPP-4 enzyme activity (typically, by 85% or more when determined in serum samples, i.e., measuring the soluble form of DPP-4), a rise in intact, biologically active GLP-1 after oral glucose or meal stimulation by a factor of 2–3, a slight light reduction fasting and a more pronounced reduction in postload glycemic excursions, along with unchanged insulin responses and suppressed glucagon responses. This pattern is exactly what can be expected from higher endogenous GLP-1 levels, that is, similar insulin responses at lower glycemic excursions prove insulinotropic activity, and reduced glucagon responses demonstrate glucagonostatic activity [26].

It may be viewed as a surprise that with near-complete inhibition of DPP-4, the intact, biologically active GLP-1 concentrations with DPP-4 inhibition only double or at most triple, since typically, only approximately 15% of GLP-1 are in the intact state (thus, theoretically, allowing for a sixfold rise when the process of degradation/inactivation is interfered with almost completely). The explanation is a feedback inhibition of L-cell (GLP-1) secretion elicited by higher concentrations of intact GLP-1 prompted by DPP-4 inhibition [27].

Sitagliptin
Sitagliptin is (2R)-4-Oxo-4-[3-(trifluoromethyl)-5,6-dihydro[1,2,4]triazolo[4,3-α]pyrazin-7(8H)-yl]-1-(2,4,5-trifluorophenyl)butan-2-amine and has a triazolopiperazine or β-amino acid-based structure [28–30]. It is a competitive inhibitor of DPP-4 and has a long half-life allowing for once daily dosing (100 mg in patients with normal renal function). Details of its pharmacologic properties are shown in Table 48.1. Sitagliptin is the DPP-4 inhibitor that has been approved for the longest time (since 2006).

Vildagliptin
Vildagliptin is 1-[[[(3-hydroxy-1-adamantyl) amino]acetyl]-2-cyano-(S)-pyrrolidine with a cyano-pyrrolidine structure [29–31]. Despite its relatively short half-life (Table 48.1), its interaction with DPP-4 is of longer duration, because it forms a covalent bond with DPP-4 that only slowly dissociates, explaining a duration of action that persists over the time characterized by high plasma concentrations. The recommended dose in patients with normal renal function is 50 mg twice daily.

Saxagliptin
Saxagliptin is (S)-3-Hydroxy-adamantyl-glycine-L-cis-4,5-methano-proline-nitrile (TFA salt) [29,32]. Its structure and mode of interaction with DPP-4 is similar to that of vildagliptin. Saxagliptin is the only DPP-4 inhibitor that is significantly metabolized to an active metabolite (5-hydroxy-saxagliptin), which contributes to the inhibition of DPP-4. Saxagliptin is metabolized by cytochrome P450 (isoenzymes 3A4 and 3A5). Potential interactions with inducers of CYP 450 or other drugs also metabolized by CYP 450 need to be taken into account. In the absence of renal functional impairment or potential interactions, saxagliptin is administered at 5 mg once daily.

Linagliptin
Linagliptin is (R)-8-(3-Amino-piperidin-1-yl)-7-but-2-ynyl-3-methyl-1-(4-methyl-quinazolin-2-ylmethyl)-3,7-dihydro-purine-2,6-dione, and has a xanthine-based structure [33]. It is a competitive inhibitor of DPP-4 with a long half-life. One special feature of linagliptin is the absence of any significant renal elimination. Therefore, linagliptin can be administered to all patients, irrespective of renal function, at a dose of 5 mg once daily. Other important pharmacologic properties are shown in Table 48.1. Linagliptin is the only DPP-4 inhibitor with appreciable protein binding in plasma.

Alogliptin
Alogliptin is 2-([6-([3R]-3-Amino-1-piperidinyl)-3-methyl-2,4-dioxo-3,4-dihydro-1(2H)-pyrimidinyl]methyl)benzonitrile [34]. Structurally, it is a modified pyrimidinedione. It has a long half-life and can, in the absence of renal functional impairment, be administered once daily at a dose of 25 mg.

Efficacy as glucose-lowering agents (reduction in HbA1c)

Monotherapy
All approved DPP-4 inhibitors lower HbA1c when studied in drug-naïve patients or at least when used in monotherapy (i.e., after washing out previous antidiabetic drug treatment in some of the patients). The approximate effectiveness is an HbA1c reduction by 0.6–0.9% relative to that seen with placebo treatment in studies lasting approximately 26 weeks. Accordingly, DPP-4 inhibitors can be used as initial drug therapy; however, only in patients who do not tolerate or have contraindications for the use of metformin. Treatment with DPP-4 inhibitors under these conditions is associated with a low risk for hypoglycemic episodes (comparable to placebo treatment) and there is little, if any change in body weight.

Add-on to oral antidiabetic agents
All approved DPP-4 inhibitors have been studied as add-on to previously existing treatment with oral antidiabetic agents like metformin, sulfonylureas, thiazolidinediones, and combinations

Table 48.1 Pharmacologic characterization of inhibitors of dipeptidyl peptidase-4 (DPP-4)

Compound: Parameter	[Unit]	Sitagliptin	Vildagliptin	Saxagliptin	Linagliptin	Alogliptin
Chemical structure	(Parent molecule)	β-Amino acid-based	Cyano-pyrrolidide	Cyano-pyrrolidide	Xanthin-based	Modified pyrimidinedione

of such agents, if the previous treatment alone did not provide glycemic control with HbA1c values in the target range. If added to metformin, DPP-4 inhibitors typically reduce HbA1c by 0.6–1.0 % relative to placebo treatment (Figure 48.3). Again, this combination is associated with a low risk for hypoglycemic episodes, and most studies have not described major weight changes. Several clinical trials comparing DPP-4 inhibitors with sulfonylureas as add-on treatment to pre-existing metformin treatment describe a similar effectiveness regarding the ability to lower HbA1c, when the study duration was between 6 months and a year. Earlier in the course of treatment, a greater

effectiveness is expected for sulfonylureas, but after a treatment duration lasting more than a year, the low "durability" of sulfonylurea-induced treatment effects improved the relative effectiveness of DPP-4 inhibitors (Figure 48.4). Typically, adding a sulfonylurea, will substantially increase the risk for episodes (with approximately one third of the patients reporting such episodes) and will induce body weight gain in the order of 1–2.5 kg.

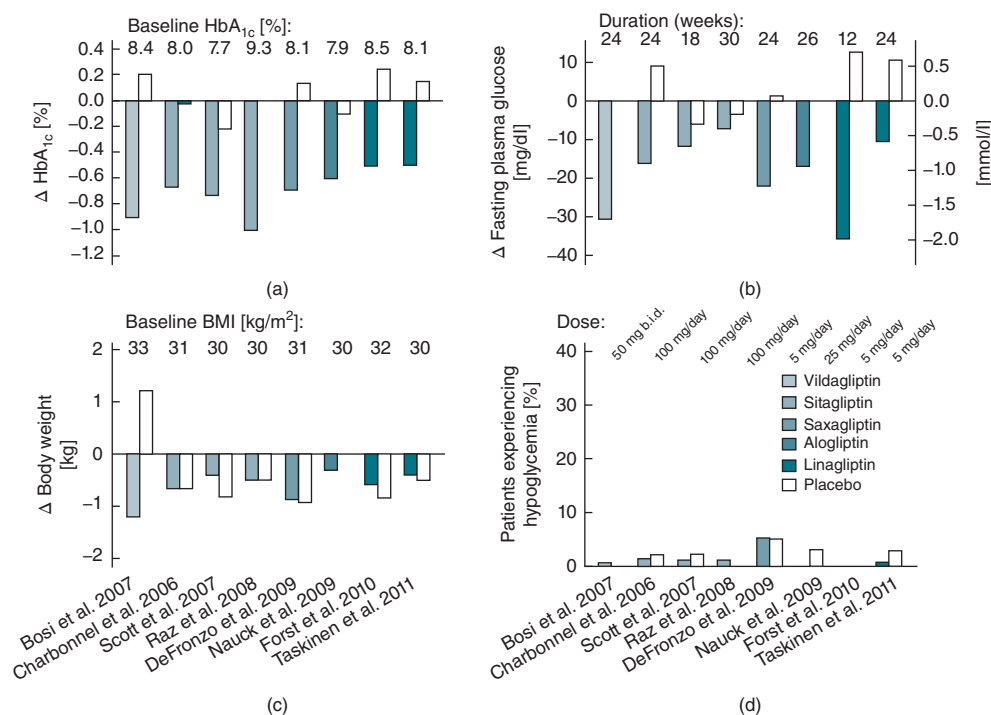
Adding DPP-4 inhibitors to pre-existing treatment with sulfonylureas (alone or in combination with metformin) lowers HbA1c to a similar degree as seen when adding DPP-4


Figure 48.3 Essential results from clinical trials with different inhibitors of dipeptidyl peptidase-4 (DPP-4) compared to placebo treatment, both administered on a background of metformin treatment. Effect on HbA1c (a), fasting plasma glucose (b), body weight (all Δ versus baseline) and proportion of patients reporting at least one episode of hypoglycemia (d). Trials can be identified by first author and year of publication. Baseline HbA1c (a), trial duration (b), baseline BMI (body mass index) (c), and dose as well as the typical interval between two administrations (d) are also indicated. For references, see [53–60].
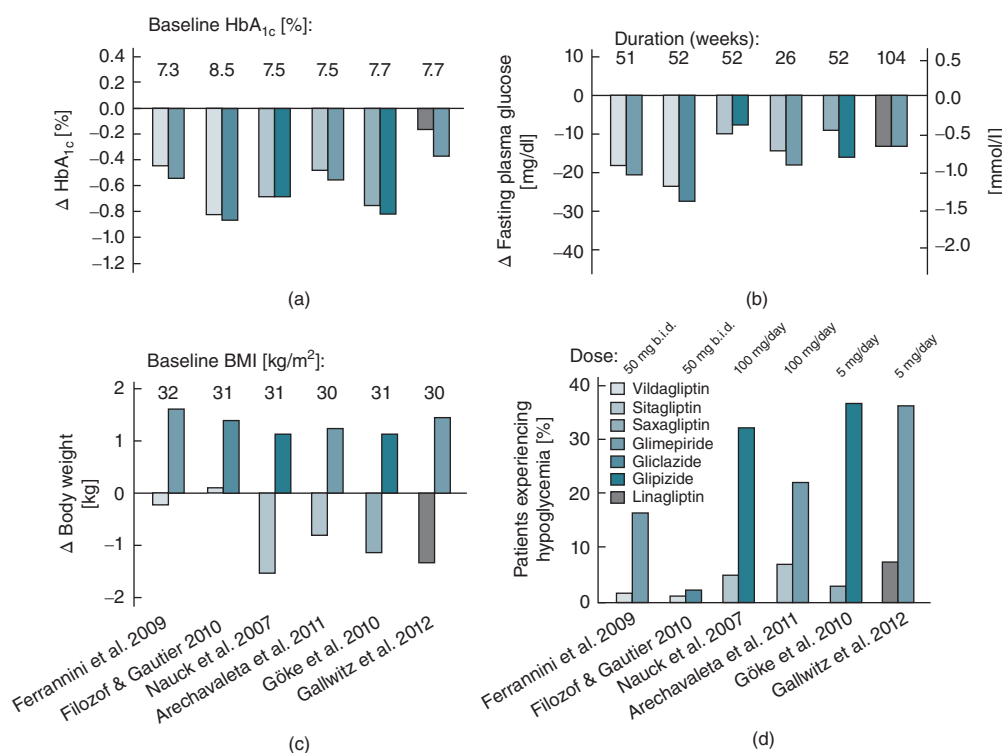

Figure 48.4 Essential results from clinical trials with different inhibitors of dipeptidyl peptidase-4 (DPP-4) compared to sulfonylurea treatment, both administered on a background of metformin treatment. Effect on HbA1c (a), fasting plasma glucose (b), body weight (all Δ versus baseline) and proportion of patients reporting at least one episode of hypoglycemia (d). Trials can be identified by first author and year of publication. Baseline HbA1c (a), trial duration (b), baseline BMI (body mass index) (c), and dose as well as the typical interval between two administrations (d) are also indicated. inhibitors to metformin. However, this combination is not characterized by the low risk of hypoglycemia that is typical for DPP-4 inhibitor monotherapy or a combination with metformin (or thiazolidinediones). Since sulfonylurea treatment alone can induce episodes of hypoglycemia, adding a DPP-4 inhibitor (and further lowering the level of glycemia and HbA1c concentrations) may elevate the risk for hypoglycemic episodes. Furthermore, in some studies this combination was associated with some (minor) weight gain.

The question arises whether, in terms of effectiveness, there are clinically relevant differences between different DPP-4 inhibitor molecules in the doses that are recommended for antidiabetic treatment (Table 48.1). All approved DPP-4 inhibitors inhibit serum DPP-4 proteolytic activity by 85% or more; in those in which this has been studied, this is associated with doubling or at most tripling GLP-1 responses after oral glucose or meals. Roughly judging from reported studies based on the ability to reduce HbA1c below baseline, no major differences in clinical effectiveness appear to exist between the different agents.

Add-on to insulin
All DPP-4 inhibitors lower HbA1c when used as add-on to insulin therapy (various regimens) and are approved for this combination [35,36]. However, the clinical trials were not designed to prove that such combinations have the potential to achieve excellent glycemic control. For example, no comparison against the preferred combination insulin plus metformin is available, nor a study proving benefits when DPP-4 inhibitors are added to insulin plus metformin. We recommend using DPP-4 inhibitors as a second choice when metformin is contraindicated or not tolerated. An interesting observation suggests that vildagliptin, when added to insulin, lowers HbA1c and the risk for hypoglycemia at the same time, possibly mediated through an improvement in α-cell responsiveness [36,37].

Comparison to GLP-1 receptor agonists
It is of interest to directly compare therapeutic effects of using GLP-1 receptor agonists (as injectable peptides) and DPP-4 inhibitors (as small molecules that can be used as oral glucose-lowering agents), since both classes of medications are incretin-based, that is, they make use of the therapeutic properties of the parent compound GLP-1 [2]. Exenatide, liraglutide [24], and exenatide once weekly [38] have been compared to sitagliptin in head-to-head comparative clinical trials in type 2 diabetic patients not sufficiently controlled on pre-existing oral antidiabetic treatment. Regarding the control of glycemia, all incretin mimetics were superior to the DPP-4 inhibitor sitagliptin, by approximately 0.3–0.5% in terms of HbA1c reduction compared to baseline values. In addition, treatment with GLP-1 receptor agonists was associated with substantial reductions in body weight (2–3 kg), whereas only minor weight reduction (<1 kg) was observed with DPP-4 inhibitor treatment. Further, the risk for hypoglycemic episodes was not markedly different for an add-on of incretin mimetics

and DPP-4 inhibitors. Nausea, vomiting, diarrhea and other gastrointestinal adverse events typically occurred with incretin mimetic, but not with sitagliptin treatment. Thus, there are substantial and typical differences in the results of treating with either GLP-1 receptor agonists or DPP-4 inhibitors. These differences are probably caused by the different levels of GLP-1 (or of the respective incretin mimetic) reached by inhibiting DPP-4 activity (a moderate rise within the "physiologic" concentration range, mostly affecting the gut, mesenteric and portal vein concentrations of GLP-1) or by administering larger doses of incretin mimetics subcutaneously (leading to circulating concentrations in the pharmacologic range, approximately 5–10-fold higher than typical postprandial physiologic levels).

Inability to provoke hypoglycemia
DPP-4 inhibitors exert their antidiabetic effects mainly through augmenting GLP-1 concentrations in response to nutrient intake, with some effect also in the basal state. GLP-1 or GLP-1 receptor agonists, even at high doses, do not themselves provoke hypoglycemic episodes. The biologic explanation is that they do not have the ability to close ATP-dependent potassium channels, which would lead to the depolarization of β cells and the subsequent release of insulin. GLP-1 increases intracellular cAMP levels, which modulate (amplify) insulin secretory responses initiated by hyperglycemia or other "primary" stimuli of insulin secretion. In line with these cell-biologic considerations, in clinical trials DPP-4 inhibitor treatment did not raise the risk for hypoglycemic episodes when used in monotherapy or on top of metformin (and/or thiazolidinediones), for example agents which themselves do not have the potential to provoke hypoglycemic episodes [2]. Rather, there appears to be a potential that endocrine pancreatic α-cell responsiveness to hypoglycemia may be improved by DPP-4 inhibitors. Whether this applies to vildagliptin only, or to other DPP-4 inhibitors as well, is unknown. If confirmed, such findings could provide a rationale to use DPP-4 inhibitors as an adjunct to insulin treatment in patients with T1DM [37] or other forms of diabetes mellitus that require insulin treatment and are associated with a risk for hypoglycemic episodes.

Nevertheless, DPP-4 inhibitors do not prevent hypoglycemic episodes provoked by sulfonylureas. Thus, in combination with sulfonylureas, DPP-4 inhibitors lose one of their typical advantages. Therefore, before using DPP-4 inhibitors together with sulfonylureas, one should carefully weigh potential advantages of such a combination against this obvious disadvantage of allowing for hypoglycemic episodes.

Weight neutrality
In most cases, treatment with DPP-4 inhibitors will not lead to major body weight changes (Figures 48.3 and 48.4). This is in contrast to GLP-1 receptor agonists, which usually induce some weight loss (Figures 48.1 and 48.2), and other classes of glucose-lowering medications like sulfonylureas, meglitinides, thiazolidinediones, and insulin, which have the potential to

induce some weight gain. GLP-1 has the potential to reduce appetite and food intake, and incretin mimetics typically lead to body weight reduction, however DPP-4 inhibitors are "weight neutral" because (a) the degree by which GLP-1 concentrations are raised is too small to exert a significant weight loss; (b) DPP-4 inhibition reduces the level of glycemia and associated glucosuria, thus without appetite reduction, some weight gain would be expected; (c) DPP-4 not only acts on GLP-1 (which is degraded and inactivated), but also on another gut peptide from the L cell, peptide tyrosine tyrosine (PYY), which is activated through DPP-4 action. DPP-4 inhibition potentially takes away weight-lowering effects mediated through GLP-1.

Adverse events

Originally, the long list of peptides with biologic activity sharing the structural features required to be a substrate of DPP-4 (i.e., with an alanine or proline residue in the penultimate amino-terminal amino acid position), gave rise to the expectation that any alteration in biologic activity in any of these putative DPP-4 substrates could be a basis for adverse events. However, no specific side effects could be predicted based on such biochemical knowledge. In contrast to expectations, adverse events reported from clinical studies involving DPP-4 inhibitors have not been shown to deviate with any frequency from those typical for placebo (in double-blind studies) or other glucose-lowering therapies with well-accepted adverse-event profiles [39]. Nor has withdrawal of DPP-4 inhibitor treatment due to drug-induced adverse events been reported with any of the agents with any noticeable frequency. Initial safety summaries reported a slightly greater occurrence of upper respiratory tract infections with DPP-4 inhibitor treatment, putatively related to a role of DPP-4 (namely, lymphocyte marker CD 26) in the immune system. More recent summaries encompassing a greater number of patients studied no longer support this finding. Certainly, DPP-4 inhibitors do not cause gastrointestinal adverse events in the same way that incretin mimetics can. There are rare reports of severe skin-related adverse events (Stephens – Johnson syndrome etc.), but a causal role regarding any one of the DPP-4 inhibitors has not been established.

Concerns and expectations regarding incretin-based therapies

To date, numerous clinical trials studying the efficacy and safety of incretin-based glucose-lowering medications have been reported, both in the classes of GLP-1 receptor agonists and DPP-4 inhibitors. While these studies provide a database for judging clinical efficacy and safety, longer term studies with clinical outcomes providing evidence that diabetic complications can be prevented or delayed are still lacking. Such studies are under way. Most of them were designed primarily to prove the cardiovascular safety of the drug in question, with a chance to document potential superiority versus a specific comparator or — in most cases — standard treatment. Outcome trials for the incretin-based glucose-lowering medications will report from 2015 on. Meanwhile, it is worth looking at more preliminary sources of evidence.

Cardiovascular risk

GLP-1 receptor agonists lower glucose concentrations, body weight, and systolic blood pressure. In addition, some nonclassical cardiovascular risk factors have been found to be reduced. These include markers of insulin sensitivity, of low-grade inflammatory responses (like high-sensitive C-reactive protein), and lower postprandial excursions of glucose and triglyceride concentrations (potentially related to a deceleration in gastric emptying). In addition, specific interactions of GLP-1 and of exenatide and liraglutide with the cardiovascular system have been described. This relates to endothelium-dependent vasodilatation and to the prevention of large necroses after induced acute myocardial infarction, with salvage of ischemic myocardium at risk induced by GLP-1 receptor stimulation [40]. Furthermore, in animal models of congestive heart failure, GLP-1 can improve pump function along with improved uptake of oxygen and glucose into the myocardium. Clinical pilot studies have supported the idea of beneficial influences of GLP-1 receptor stimulation in the short term [40]. The mechanisms are not quite clear. GLP-1 receptors (of the well-described "pancreatic" type) are expressed in the cardiovascular system, but in pharmacologic studies, cardiovascular effects have been described not only for GLP-1 of the intact, biologically active sequence (GLP-1 (7-36 amide) or (7-37)), but also for the DPP-4 degradation products (GLP-1 (9-36 amide) or (9-37)), which are inactive at the pancreatic GLP-1 receptor. Conversely, exendin-4, which is a high-affinity ligand at the pancreatic type GLP-1 receptor, was sometimes found to be less effective than GLP-1. Taken together, these findings suggest that there may be a second GLP-1 receptor, specifically expressed in the cardiovascular system, with a substrate specificity different from the well-characterized GLP-1 receptor that mediates the insulinotropic activity of GLP-1 at the level of the β cell [40].

While clinical trials with cardiovascular events as their main endpoints are under way with most of the approved incretin-based medications, preliminary analyses based on adverse events reported from phase 3 trials indicate a trend for reduced numbers of acute myocardial infarctions, stroke, and cardiovascular death [41]. Therefore, it is reasonable to hope that these trials will confirm the cardiovascular safety of GLP-1 receptor agonists and DPP-4 inhibitors, with a potential to detect a benefit, either based on the immediate consequences of improved glycemic control, the effects on body weight and cardiovascular risk factors associated with such changes, or based on additional, specific interactions with the cardiovascular system.

Acute pancreatitis

Acute pancreatitis has been diagnosed in patients treated with GLP-1 receptor agonists or DPP-4 inhibitors. The question is

whether there is any causal relationship, leading to an increased risk for acute (or chronic) pancreatitis induced by such treatment. Animal experiments have described histologic changes compatible with acute or chronic pancreatitis after treatment with sitagliptin and exenatide, but with different experimental design, no such changes or even anti-inflammatory changes have been documented with liraglutide treatment. Epidemiologically, several analyses of claims databases have uniformly described the absence of an elevated risk for pancreatitis [41]. The notable exception is an analysis of the FDA adverse events reporting system that found a several-fold elevation in the risk of pancreatitis as well as pancreatic cancer [42]. The circumstances of this analysis (i.e., the timing of collecting data) suggest the influence of a number of different potential reporting biases. In all, the question of incretin-based medications promoting pancreatitis must be regarded as an open one, however, with the bulk of available data not supporting a major risk [41]. Acute pancreatitis usually is diagnosed when at least two out of three criteria are fulfilled: (a) typical symptoms including severe abdominal pain, usually leading to presentation at an emergency department; (b) elevated lipase or amylase activity in plasma; and (c) findings supporting the diagnosis using imaging procedures. Recent findings from clinical trials with incretin-based medications have shown that patients with T2DM often (approximately 20%) display elevated pancreatic enzyme levels at screening examinations, even when they did not report symptoms suggesting pancreatitis. In a study employing liraglutide treatment, pancreatic enzyme levels slightly rose after exposure to the drug. While this indicates some interaction of GLP-1 receptor stimulation with the exocrine pancreas, it does not necessarily indicate the initiation of inflammatory changes. The nature and consequences of this interaction need to be better defined. However, it appears possible that acute pancreatitis has been over-diagnosed in patients with elevated enzymes, but without appropriate symptoms (and ensuing work-up) supporting the diagnosis of acute pancreatitis, especially in patients treated with drugs that typically cause gastrointestinal adverse events. In conclusion, it appears wise to suggest caution when using GLP-1 receptor agonists in patients with a history of acute pancreatitis, and to discontinue treatment if suspicion or diagnosis of acute pancreatitis arise.

Pancreatic carcinoma

Some animal studies have described histologic changes compatible with chronic pancreatitis and an increased pancreatic ductal proliferation rate after treatment with exenatide or sitagliptin. Sometimes, this was associated with more pancreatic duct glands (PDGs: outpouches from major pancreatic ducts) or low-grade pancreatic intra-epithelial neoplastic lesions (PanINs), which are thought to represent preneoplastic lesions associated with the transition from chronic pancreatitis to pancreatic carcinoma. On the other hand, the bulk of animal toxicology data from all development programs of incretin-based glucose-lowering medications has not reported any such changes, and specific studies with long-term, high-dose exposure of animals to incretin-based drugs have not confirmed a uniform influence of incretin-based medications to support the development of such histologic changes. Case reports of pancreatic cancer developing after initiating incretin-based treatment in patients with a previously normal pancreatic morphology have not been reported, and the natural history of the development of pancreatic cancer is thought to be a slow process, with little chance to alter its course within a few years (the longest exposure possible to date). The more surprising was the finding, again from the analysis of the FDA adverse events reporting system, that exenatide and sitagliptin treatment were associated with an elevated risk for the diagnosis of pancreatic cancer [42]. Again, better surveillance of such events with incretin-based medications is necessary to define or rule-out a potential risk in the long term [41].

C-cells, medullary thyroid carcinoma

In rodents, there is a high prevalence of C-cell abnormalities including hyperplasia, adenomas, and spontaneous C-cell (medullary thyroid) carcinomas. Liraglutide treatment increases the prevalence of C-cell disease, including medullary carcinomas, especially in male rats. This finding gave rise to the question whether there could be a risk of increasing the incidence of this rare endocrine tumor in patients treated with GLP-1 receptor agonists. Again, a higher risk for thyroid carcinoma (irrespective of the histologic type) was suggested by the analysis of the FDA adverse events reporting system [42]. In rodent C-cells, GLP-1 receptor expression is prominent, their stimulation (by any ligand) will raise cAMP and lead to secretion of calcitonin, and probably induces proliferative changes [43]. In human C-cells, cAMP levels and calcitonin are not affected, so it is questionable whether any proliferative responses can be expected [43]. Whether or not follicular cells and malignant cells from different varieties of thyroid carcinomas express GLP-1 receptors is unknown. Controversial findings have been reported. Cases of thyroid carcinoma diagnosed after initiation of GLP-1 receptor agonist treatment in patients with previously normal thyroid morphology have not been reported. In all, at present the possibility of inducing a higher risk for medullary (or other histologic types of) thyroid carcinoma can neither be totally refuted nor confirmed. Better surveillance will hopefully clarify this point in the long term. Based on the low incidence of especially the medullary variety of thyroid carcinomas the risk will most likely be low. Patients with a genetic trait predisposing to medullary thyroid carcinomas (hereditary medullary thyroid carcinoma or multiple endocrine neoplasia type 2) should not be treated with GLP-1 receptor agonists. There are no critical findings regarding DPP-4 inhibitors with respect to thyroid carcinomas.

Clinical use of incretin-based medications

While clinical trials in patients who had been drug-naïve or washed-out from previous treatment with oral antidiabetic

agents have shown the clinical effectiveness of both GLP-1 receptor agonists and DPP-4 inhibitors, they usually are employed in this patient population only when metformin is contraindicated or not tolerated. In most patients, DPP-4 inhibitors or GLP-1 receptor agonists are used as a second- or third-line glucose-lowering agent, added to previously used metformin treatment, when glycemic control is no longer adequate with monotherapy. In principle, they compete, at this stage of treating T2DM, with sulfonylureas or meglitinides, with thiazolidinediones, α-glucosidase inhibitors, or insulin. DPP-4 inhibitors, which are administered as tablets for oral ingestion, tend to be used at earlier stages, when injectable therapy does not need to be considered to achieve individual glycemic targets. GLP-1 receptor agonists, as injectable treatment, will typically be considered at later stages, when otherwise insulin would have to be considered as an alternative treatment.

DPP-4 inhibitors versus sulfonylureas

As add-on to metformin treatment, sulfonylureas had been popular; however, their use was associated with a risk for hypoglycemia (sometimes requiring professional help or even hospitalization, and in rare cases leading to death) and with weight gain. In addition, epidemiologic data have suggested some risk for more cardiovascular events and increased mortality, although this has not been confirmed in prospective studies, especially the UKPDS. As a result of these potential adverse effects, the use of sulfonylureas has been declining over the past years. Rather, DPP-4 inhibitors have been increasingly used. Head-to-head comparisons (e.g. Figure 48.4) have shown that the ability of a variety of DPP-4 inhibitors to control glycemia is comparable to the effectiveness displayed by sulfonylureas (Figure 48.4). Most comparisons observed a better reduction in fasting glucose concentrations by sulfonylureas, indicating a more prominent postprandial action of DPP-4 inhibitors. DPP-4 inhibitors induce some minor weight reduction, while sulfonylureas uniformly raise body weight by approximately 1–2 kg. Up to one third of the patients treated with sulfonylureas experience at least one episode of hypoglycemia over a period of 26–52 weeks, possibly with differences between different members of the sulfonylurea class. Of particular interest may be the fact that in a direct head-to-head comparison of the sulfonylurea glimepiride with the DPP-4 inhibitor linagliptin there was a significant difference in cardiovascular outcomes in favor of linagliptin treatment, albeit at a relatively low total number of events [44]. A similar trend had been noted for the comparison of other sulfonylureas with a variety of DPP-4 inhibitors previously. Thus, for patients who need to avoid hypoglycemia or who intend to reduce body weight, DPP-4 inhibitors may be preferable.

GLP-1 receptor agonists versus insulin

As injectable therapies, insulin and GLP-1 receptor treatment are often considered when a combination of oral antidiabetic agents is no longer able to control glycemia within individually agreed treatment targets for HbA1c and plasma glucose. Theoretically, insulin treatment can achieve any reduction in plasma glucose concentrations that is required, even in severely hyperglycemic patients, depending on finding and employing the appropriate dose(s). GLP-1 receptor agonists, which are used at standard doses that are usually not varied with the effects achieved, have whatever clinical effectiveness is associated with the use of the particular dosage. Thus, the preoccupation was that comparing GLP-1 receptor agonist treatment with insulin treatment would be a bold comparison, with a great likelihood that insulin therapy would be more effective. In several clinical trials comparing exenatide (twice daily), liraglutide, or exenatide once weekly with either insulin glargine or premixed insulin (Figure 48.4), the effectiveness of using a GLP-1 receptor agonist was at least equal to that of insulin treatment. In some, but not all of these trials, insulin was better in controlling fasting glucose, indicating a more pronounced postprandial mode of action (deceleration of gastric emptying etc.) in the case of GLP-1 receptor agonists. It had to be discussed whether the dosage of insulin used was adequate and allowed a full exploitation of the therapeutic potential inherent in insulin-based treatment regimens. Most likely, insulin titration in such clinical studies could potentially be optimized, but was very similar to the way insulin treatment is administered in clinical practice. Insulin treatment, even intensified regimens with multiple daily injections, do not guarantee goal achievement. Experience or fear of weight gain or of hypoglycemic episodes may limit efforts to stringently increase insulin doses as determined by a treat-to-target algorithm. Along these lines, GLP-1 receptor agonist treatment may be particularly better in reducing HbA1c in the patient most difficult to treat, such as those with high baseline HbA1c. Based on this experience, it may no longer be justified to assume that insulin-based treatment regimens are the ultimate escalation step in the treatment of T2DM patients, for whom other approaches have failed. Of course, there is the possibility to combine long-acting insulin with GLP-1 receptor agonists [19,20], a regimen that may successfully compete with intensified insulin regimens as the most effective treatment regimen for those not achieving their goals with oral antidiabetic agents and long-acting insulin alone.

Recommendations for special populations

Subgroups of patients with special characteristics, such as higher age, impaired renal function, impaired kidney function, or gastrointestinal diseases, which could potentially interfere with the mode of action of a therapy that depends on the interaction of a gastrointestinal hormone (GLP-1) with its receptor, need special consideration regarding the use of incretin-based glucose-lowering medications.

Renal functional impairment

GLP-1, like other gastrointestinal hormones (including the partner incretin hormone GIP), is eliminated renally. Patients with significant functional impairment of their kidneys (i.e., a

Table 48.2 GLP-1 receptor-agonists (incretin mimetics)

Compound	Initial dose (subcutaneous injection)	Maintenance dose (subcutaneous injection)	Administration frequency	Homology to GLP-1 (amino acid sequence)	Antibody formation (% of patients treated)
Exenatide (unretarded)	5 µg	10 µg	Twice daily	53%[a]	40–50%
Liraglutide	0.6 mg	1.2 mg (1.8 mg)	Once daily	97%	<8%
Exenatide once weekly	2 mg	2 mg	Once weekly	53%[a]	50–70%
Albiglutide[b]	30 mg	50 mg	Once weekly	97%	Not known
Lixisenatide[b]	10 µg	20 µg	Once daily	53%[c]	Not known

[a]Plus carboxy-terminal extension by 9 amino acids.
[b]Approval expected 2013.
[c]Plus carboxy-terminal extension by 5 amino acids (versus exenatide) or by 14 amino acids (vs. GLP-1 (7-36 amide)), respectively (see Figure 48.5).

reduced estimated glomerular filtration rate) are characterized by elevated concentrations of such gastrointestinal hormones. Exenatide is also characterized by a significant renal elimination. Thus, a higher exposure is expected in renally impaired patients when using standard dosage regimens (Table 48.2). With mild reductions in eGFR, exenatide can be used, dose reductions (e.g. maintenance at 5 µg twice daily) may be recommended, and at severe chronic renal failure (below an eGFR of 30 mL min^{-1}), exenatide treatment cannot be recommended. Liraglutide is not eliminated via the kidneys to the same degree, but there is little experience in patients with reduced eGFR, so it should be used with caution.

Most DPP-4 inhibitors (sitagliptin, vildagliptin, saxagliptin, alogliptin) are characterized by predominant renal elimination. Thus, in patients with significant reductions in eGFRs, the dose needs to be reduced, in one step (in the case of vildagliptin and saxagliptin) or in two steps (in the case of sitagliptin and alogliptin). These recommendations are based on experience from clinical studies in populations that demonstrated a similar effectiveness (in terms of HbA1c reduction) as is typical in patients without renal functional impairment, along with a similar safety and tolerance. The notable exception is linagliptin, which is characterized by a predominantly biliary excretion and negligible renal elimination, which can be used across the stages of chronic kidney disease at the standard dose of 5 mg per day. For details, see Table 48.1. It should be noted that other antidiabetic medications typically used in a population of patients with T2DM and renal functional impairment, such as sulfonylureas, also need to be dose-adjusted or to be used with caution, in case accumulation increases the risk for hypoglycemic episodes.

Liver disease

Liver diseases that need to be considered are diabetic fatty liver (steatosis or steatohepatitis), which are highly prevalent in an obese, type 2 diabetic population, and advanced liver disease (fibrosis, cirrhosis), which may be associated with impaired liver function as far as synthesis/secretion of liver-derived proteins including albumin, blood clotting factors, etc., and detoxification/elimination function are concerned.

Both obesity, caloric excess, and loss of glycemic control predispose to fatty liver. Besides thiazolidinediones, which specifically remove triglycerides from the hepatic parenchyma and promote storage in subcutaneous adipose tissue depots, GLP-1 receptor agonists are a second class of glucose-lowering agents that may be associated with a specific benefit in patients with fatty liver disease. Supporting findings are from animal experiments or preliminary clinical evidence. The main effect may be a consequence of incretin-mimetic-induced weight loss, but more specific interactions with hepatic triglyceride metabolism, inflammation, etc. appear possible. Among the DPP-4 inhibitors, vildagliptin is hepatically metabolized and sometimes has increased liver enzymes, leading to the recommendation of monitoring transaminases. Thus, vildagliptin is not the preferred treatment in the face of liver disease.

Gastrointestinal disease

GLP-1 receptor agonists may delay gastric emptying. Their use should be avoided in patients with clinically significant retardations in gastric emptying, that is, with a diagnosis of severe autonomous neuropathy of the gastrointestinal tract including symptomatic diabetic gastroparesis. This, however, is rarely diagnosed in patients with T2DM, even after long duration of the disease. A deceleration of gastric emptying may accentuate regurgitation of gastric content in patients prone to gastroesophageal reflux disease. Patients with constipation due to intestinal autonomic neuropathy may be at risk for worsening symptoms when treated with incretin mimetics. These considerations do not apply to the clinical use of DPP-4 inhibitors.

Recommendations by guidelines for the treatment of type 2 diabetes

Guidelines, recommendations, and suggested treatment algorithms issued before 2007 did not generally make reference to incretin-based medications [45] as GLP-1 receptor agonists and DPP-4 inhibitors had not been available long enough at that time. A treatment algorithm issued by the American Diabetes

a. GLP-1 [7-36amide]
b. Exenatide (exendin-4, Amylin/Eli Lilly & Co./Bristol-Myers-Squibb)

c. Liraglutide (NovoNordisk)
d. Lixisenatide (Sanofi)

e. Sitagliptin (Merck)   **f. Vildagliptin (Novartis)**   **g. Saxagliptin (AstraZeneca, Bristol-Myers Squibb)**
h. Alogliptin (Takeda)   **i. Linagliptin (Boehringer Ingelheim)**

Association and the European Association for the Study of Diabetes in 2009 mentioned GLP-1 receptor agonists, however, among "less well-validated therapies" for T2DM [46]. An official statement of the American Association of Clinical Endocrinologists from 2009 gives specific recommendations for the use of both classes of incretin-based antidiabetic medications, with an emphasis on dual and triple therapy including such agents [47]. The British National Institute for Health and Care Excellence (NICE) clinical guideline 87 gives detailed recommendations for employing GLP-1 receptor agonists and DPP-4 inhibitors,

for example suggesting entry criteria for such treatment (like a minimum degree of obesity in the case of incretin mimetics) and recommending continued treatment with such agents only when clinical effects have been documented individually (http://www.nice.org.uk/nicemedia/pdf/CG87QuickRefGuide .pdf). The latest position statement by the American Diabetes Association and the European Association for the Study of Diabetes issued in 2012 is based on the principle of individualized approaches offering medications that best help attain individual treatment targets. Since these often include the avoidance of hypoglycemic episodes and weight gain, such objectives may speak in favor of using incretin-based medications [48].

Future developments

In the coming years, we can expect important new developments in the treatment of T2DM with incretin-based drugs, both regarding new agents in both classes and more results of clinical trials with relevant clinical endpoints, including cardiovascular outcomes. The latter information will certainly help to define the value of incretin-based medications for the prevention of diabetic complications. Such studies will also help understand the open questions regarding pancreatitis and pancreatic carcinoma, as well as (medullary) thyroid cancer. Regarding novel compounds within the classes of GLP-1 receptor agonists and DPP-4 inhibitors, a substantial number of incretin mimetics are under development, among them albiglutide, lixisenatide, dulaglutide, semaglutide. They are mainly designed for less frequent administration, for example once-weekly injections, which, it is hoped will improve adherence to treatment. Whether it will be possible to improve the relationship between effectiveness and side effects is an open question. Given the differences observed between different compounds, there seems to be space for further improvements. Within the class of DPP-4 inhibitors, this appears more difficult, since all available compounds have similar glucose-lowering potency and are virtually free from drug-induced adverse events. There is an opportunity for longer inter-administration intervals in the class of DPP-4 inhibitors as well. Deeper understanding of the mechanisms of action, however, may present clues for further improvements regarding effectiveness as well.

Insulin pumps

Dace L. Trence and Irl B. Hirsch

University of Washington School of Medicine, University of Washington Medical Center-Roosevelt, Seattle, WA, USA

Key points

- Insulin pump technology has advanced to now include computer-assisted insulin dosing, incorporating glucose data, carbohydrate counting, and insulin tracking.

- Continuous glucose sensors added to insulin pump technology have further advanced self-management of diabetes mellitus.

- Optimal patient use of this technology requires support in learning how to use these tools, and in the case of continuous glucose sensors, requires ongoing patient attention and use of data obtained.

- Future advances in the integration of insulin delivery in response to glucose sensing are evolving with attention to low-glucose sensing and automatic pump insulin delivery as a first step toward a fully automated artificial pancreas model.

- Clinicians should be aware and ideally comfortable with evolving technology to facilitate the ability to present, as well as support, these tools in directing and supporting the self- management of diabetes of their patients.

History

Insulin pump or continuous subcutaneous insulin infusion (CSII) technology was in its infancy in the 1960s when Dr. Arnold Kadish in Los Angeles, CA first conceptualized a closed loop system which provided the components of blood glucose sensing coupled with insulin infusion [1]. Designed to be worn on the back to facilitate intravenous access, it was certainly portable but was also very large and cumbersome which proved to be a major drawback. This insulin pump prototype was comprised of a glucose autoanalyzer to measure blood glucose, coupled to an on/off switch operating a pump that delivered insulin. When the autoanalyzer detected glucose levels outside the normal range, insulin was automatically turned off. In the next decade, a new device called the Biostater became available and touted computer-controlled glucose sensing and insulin delivery system. However, it also fell to the wayside due to its unwieldy size and lack of portability.

The Biostater consisted of multiple components: a pump that withdrew blood for analyses, a glucose analyzer for continuous glucose determinations, computerized algorithms for calculating insulin or dextrose amounts to be infused based on glucose blood levels, a computer-driven infusion pump for insulin or dextrose delivery, and a print out of blood readings based on per minute determinations [1]. Primarily, this device was used in research, although it was also used in obstetrical arenas.

The next iteration of the insulin pump was designed to be worn as a shoulder bag in an attempt to overcome the portability issues of previous designs. Slama et al. [2] reported on this insulin delivery system that provided insulin over 1–5 days, a basal insulin at a constant rate, with prandial insulin boluses at a set 15-fold higher rate. Unfortunately, progress with this model was hampered by insulin delivery being intravenous and the consequent risks of infection, thrombosis, and phlebitis. Further advancement of a portable design was accomplished at the National Institute for Medical Research in England. The Mill Hill Infuser, first developed for research entailing infusing hormones into animals, could deliver insulin in a dual rate process: a basal rate and a prandial rate that was eightfold higher. Delivery was available at the push of a button with a battery-driven syringe pump of a dramatically reduced size and weight of only 5.6 ounces—about a third of a pound [3].

Technology continued to progress with the first commercial pump sold on the market in 1978 under the name AutoSyringe, commonly referred to as the "Big Blue Brick" due to its appearance. Early sales surpassed expectations at 600 pumps per month, sparking interest in commercial pump development by many device companies in the early 1980s [4]. Numerous setbacks occurred at first due to problems with safety of insulin delivery, limited safety alarms, little flexibility in insulin dosing, needles that were metal and dislodged frequently, and batteries that required frequent recharging [1]. Some models even required a screwdriver to adjust insulin doses (http://www.medscape.org/viewarticle/460365_2 (accessed August 27, 2012)). Not surprisingly, complications from lack of glucose

control, such as diabetic ketoacidosis, hyperglycemia, and infection at the insertion site were common [5]. Bulkiness continued to impair the appeal of insulin pumps as many weighed up to a pound and were the size of a house brick. These early pump prototypes were more likely to be prescribed for those with diabetes that was difficult to manage, not infrequently giving less than expected benefit, in turn dampening patient as well as prescribing clinician enthusiasm for personal pumps.

The 1990s provided a true evolution in technological advances that allowed insulin pumps to become much safer and reliable devices. Improvements to reduce insulin leakage, provide more consistent insulin delivery, and address tubing occlusion, along with more reliable alarms for these potential malfunctions, boosted user safety. Alarms for low battery or low insulin amount in the pump reservoir increased users' sense of security in depending on insulin pump therapy. Clearly, more reliable pump devices led to a new level of comfort in prescribing these for more people with diabetes, not limiting this technology to those with only the most challenging need to treat diabetes.

Pumps now function even more effectively by storing multiple preprogrammed basal insulin rates in their memory. Bolus doses can be determined by entering the carbohydrate content of an upcoming meal, as well as a glucose target range, and a correction factor for not only pre-meal glucose adjustment, but also for glucose correction outside the meal setting. The concept of insulin on board based on the pharmacodynamics of rapid analogue insulin [6] allows for the ability of the pump to calculate a more precise correction insulin dose—typically a more beneficial dose than would be apparent to the pump user, who might be tempted to guess at a correction dose! These so called "smart pumps" can also deliver insulin boluses to prolong the action of the insulin activity. Extended boluses are beneficial for higher fat and protein meals such as a burger and fries or pizza—where the impact of carbohydrate can be dramatically delayed. The risk of pre-meal hyperglycemia is also reduced as extended boluses can be given with a proportion of the total dose initially given normally. Unfortunately, there is a learning curve with this feature and a lot of trial and error is necessary for maximum efficacy. Nevertheless, the introduction of continuous glucose monitoring has taken some of the guess work out of extended boluses. Another aspect of extended boluses allows for an increase in temporary basal insulin. Situations in which the user is engaged in a prolonged period of snacking, such as a wedding reception, are ideal for this feature as snack foods are typically high in carbohydrates.

Additionally, pump manufacturers have listened to their customers as evidenced by the variety of options now available. Pump encasements come in a rainbow of colors, LED screens and digital displays ensure easier visualization of menu options, and tubeless insulin delivery systems based on a pod containing an insulin reservoir and pump are operated by a remote computerized hand- held device allowing more discretion.

With regard to size, pumps are dramatically smaller and resemble a credit card in size. Such developments have device manufacturers appealing to a growing market of demand. The global insulin pump market was valued at $586.4 million in 2009, and is forecast to grow at a compound annual growth rate of 9% from 2009 to 2016. Market growth is attributed in part to rising patient awareness. In the US for the same time frame, the same rate of growth is expected bringing it to $843 million in 2016. The traditional insulin pump segment was valued at $394 million in 2009. And there is an emerging disposable insulin pump market, valued at an additional $58.9 million in 2009. Clearly pump therapy has developing appeal and the US holds the largest share of the global market (http://www.mtbeurope.info/content/ft1008001.htm (accessed September 3, 2012)).

Further enhancing pump technology is the ability to link it to continuous glucose sensing. By combining the ability to look at glucose trends to allow for insulin adjustment and deliver insulin the concept of an "artificial pancreas" may be realized. Current technology is not yet advanced to the point where the pump user can become a "disinterested bystander." A system that senses low glucose via continuous sensor (a glucose level programmed by the user) resulting in an automatic suspension of insulin delivery by pump for 2 hours, then automatic restart at preprogrammed basal delivery rate, has been released for use in most of the world and at the end of 2013, also in the United States.

Along with reviewing the rewards of constantly evolving technology it is also prudent to consider the drawbacks and identify the future course of insulin pump therapy. Clearly more sophisticated features have improved safety. Notably, pumps boast programmable memory, lockout alarms, lack of bolus over time alarms, maximum bolus delivery locks, and ability to download pump memory to check insulin delivery. Even with numerous safety features, there are no guarantees since users may ignore alarms, forget settings and fail to check them when replacement or refurbished pumps are needed. Additionally, successful pump therapy relies on two key components prior to initiating pump therapy. First of all, accurate pump settings need to be determined by a team working closely with the user [7]. Secondly, although there are clinical situations where pump therapy can be more successful than multiple daily insulin dosing (MDI) injection therapies [7], the ability to optimally improve glycemic control routinely depends on extensive individualized education prior to initiating pump therapy. Typically, the process requires education in insulin pharmacokinetics as well as pharmacodynamics, the concept of lag time between insulin bolus and meal ingestion, the use of correction dose insulin, and carbohydrate counting [7]. The use of a multidisciplinary team for pump therapy cannot be underestimated for best results. Even friends or community members could potentially act as resources, although data to support this is needed. It is both notable and unfortunate that a multidisciplinary team approach is limited in the majority of primary care, and even in many endocrinologists' clinical practices.

Efficacy, benefits, data supporting insulin pump therapy

We are in an age that demands the use of scientifically evidence-based practices for prescribed care modalities. Given the typical $7000 price tag to get started on a pump, even users with an average insurance policy covering 80% find themselves burdened with a large expense. Both users and providers must consider whether the investment is justified by the benefits. For starters, where has pump therapy been shown to have a favorable impact on glycemic control? Are there indications that it helps to prevent the complications of diabetes? And are there specific populations, for which data suggest a stronger benefit, or for whom there is a limiting factor to consider for the potential use of an insulin pump?

Whether the pump user is young or old, studies reveal that age is not a limiting factor. Plotnick [8] followed 95 patients who began insulin pump therapy with a mean age of 12.0 years (range 4–18), 29% being <10 years old, for a median duration of 28 months. A small but significant decrease in HbA1c at 3–6 months after pump start (7.7 vs. 7.5%; $p = 0.03$) was followed by a gradual HbA1c increase. After adjusting for diabetes duration and age, mean HbA1c after pump start was significantly lower than before pump start (7.7 vs. 8.1%; $p < 0.001$). The number of medical complications (diabetic ketoacidosis, emergency department visits) was similar before and after pump start. On the plus side, there tended to be fewer hypoglycemic events after pump start (12 vs. 17; rate ratio 0.46; 95% CI 0.21–1.01).

Sulli [9] reported on 42 patients (mean age 12.2 +/− 3.4 years; range 4.5–17 years; 24 males; mean duration of T1DM 5.1 +/− 3.0 years) followed over 4 years. Mean HbA1c levels prior to pump initiation at 8.9 +/− 1.0%, decreased during the first (8.2 +/−0.9%; $p = 0.00$), second (8.6 +/− 1.0%; $p = 0.05$), third (8.4 +/− 0.9%; $p = 0.01$), and fourth (8.2 +/− 1%; $p = 0.00$) year of pump (CSII) therapy. Insulin requirements (U kg^{-1} per day) decreased during CSII treatment compared with multiple daily insulin dosing (MDI) treatment. Through the first, second, third, and fourth years of follow-up the number of episodes of severe hypoglycemia (20.0, 20.0, 20.0, and 0 episodes/1000 patient-years, respectively) and diabetic ketoacidosis (0.05, 0.00, 0.03, and 0.00 episodes/patient per year, respectively), events were similar to that in the year preceding CSII therapy (20.0 and 0.03, respectively), suggesting no increase in ketoacidosis episodes on CSII therapy in this young population.

De Bock [10] reported a 6-year retrospective analysis of children with T1DM started on insulin-pump therapy from 2002 to 2008 compared to the MDI user T1DM population matched by age, sex, ethnicity, and duration of diabetes. Transitioning to insulin-pump treatment was associated with an improvement in HbA1c compared with baseline (−0.3% per year; $p < 0.001$) for up to 3 years. In contrast, nonpump controls showed a continuing trend to higher HbA1c values (+0.2% per year; $p < 0.01$). The risk of severe hypoglycemia fell after pump start (from 27 to 5 events/100 patient-years) with no change in nonpump controls; the rate of diabetic ketoacidosis was low in both groups, and not different.

Fuld [11] reviewed the literature on children and insulin pump use, and noted the discrepancies between randomized and nonrandomized control study results with nonrandomized studies showing a consistent fall in HbA1c of up to 0.9% with reduced frequency of hypoglycemia in the patients switched from MDI to CSII. This was not consistently seen in the randomized studies. However, Kapellen [12] reported on 1567 German and Austrian children and adolescents with T1DM who were placed on CSII between 1995 and 2005 from MDI, 138 of whom were under 5 years of age. The major indication (42.5%) for switching from MDI to CSII was to reduce severe hypoglycemic events. And indeed the rate of severe hypoglycemic events decreased from 52.1 per 100 patient-years to 24.8 per 100 patient-years ($p < 0.001$) after 1 year of pump therapy. Additionally these lower rates were not associated with a deterioration of glycemic control (HbA1c, 7.6% vs. 7.5%). So although there is inconsistency in HbA1c impact, there is clearly less hypoglycemia, a suggestion of less weight gain, and no increase in ketoacidosis in children on CSII.

In contrast, quality of life improves for parents whose children are started on CSII, as evidenced by multiple studies [13]. The studies also noted that children did not return to MDI after being switched to CSII when the studies were completed, reflecting a preference for pump therapy. Hypoglycemia and related seizures are a major parental fear, which can adversely impact the ability to find appropriate childcare. Interestingly, Weinzimer [14] found that children who received daytime care from paid caregivers, such as nannies and daycare centers, had an even greater improvement in HbA1c levels, from $7.5 \pm 0.9\%$ pre pump to $7.1 \pm 0.8\%$ post pump ($p = 0.002$), provided caregivers had been instructed on CSII and had ready access to parents via telephone or beeper.

Sullivan-Bolyai et al. [15] interviewed parents of children on pump therapy to assess their experiences. Despite initial hesitation about pump therapy, parents reported becoming comfortable between 10 days to 3 months after the start of CSII. In fact, all family members reported feeling more freedom and flexibility in their daily lives. Improved marital relationships were also reported, as well as the benefits that CSII "gave them their children back," children were "in a better mood" and had increased school concentration. Even in comparing CSII to MDI in preschoolers, specific to psychosocial measures targeting parent and child psychological adjustment, parents reported a significant decrease in diabetes-related worry with CSII [16]. Clearly, the studies are consistent in showing improved quality of life in families with a child on CSII, which led to a position statement in 2006, by the Lawson Wilkins Pediatric Endocrine Society [17] that stated that all children with diabetes, regardless of age, should be "considered potentially eligible" for CSII. They further stressed that families should be made fully aware of

the expectations of CSII treatment and what CSII "can and cannot do."

In the elderly, there is little evidence supporting that older patients treated with insulin pump therapy have improved clinical outcomes compared to patients treated with MDI [18]. The effectiveness of MDI with currently available insulin analogues used in basal-bolus insulin regimens provides a very effective alternative to pump therapy. Hirsch et al. [19] reported 100 patients with T1DM from all age groups randomized to either MDI using aspart before meals and glargine at bedtime or to CSII for 5 weeks and then crossed patients over to the alternate treatment group for an additional 5 weeks. Although fructosamine levels were significantly lower and glucose exposure profiles improved in the CSII periods of treatment, no differences were noted in the frequency of hypoglycemia. The mean age, was 43 ± 11.1 years with a range of 30–55 years, and there was no stratification of outcomes by specific age. Regardless, it is reasonable to assume that similar outcomes would be noted in the youngest as well as the oldest groups of patients.

A Cochrane Review [20] evaluated 23 studies with 976 participants with T1DM randomized to CSII versus MDI and noted a statistically significant difference in HbA1c *favoring* CSII (weighted mean difference, -0.3 (95% CI, -0.1– 0.4)). Also noted were that patients with severe hypoglycemia benefited from CSII and reported improvements on quality of life measures. No significant differences were seen in body weight changes, nonsevere hypoglycemia events, morbidity, mortality, or costs. However, the conclusion for cost in this review was curious, as it was not based on differences in benefits, and was referred to as not available in any study, but was none the less estimated as the additional cost associated with using CSII over MDI, reported as varying from £1091 (€1208, 11/2009 exchange rate) to £1680 (€1860, 11/2009 exchange rate), per year (including the cost of the pump and consumables). Despite some evidence for benefit with CSII, the Cochrane Review dataset had few patients in older age groups, making it difficult to extrapolate its findings to the elderly.

Only one randomized trial has compared efficacy and quality of life in older adults (mean age, 66 years) randomized to either CSII or MDI. In this study, Herman et al. [21] followed 107 adults with T2DM (mean HbA1c, 8.2%) treated with insulin for 12 months. Patients were not selected on the basis of having failed MDI therapy or having achieved suboptimal results. No statistically significant differences were noted in HbA1c lowering, hypoglycemia frequency, weight gain, treatment satisfaction, or quality of life measures between the MDI and CSII groups. However, Rizvi et al. [22] sought to describe the experience of a subset of older patients (mean age, 66.4 years) with T1DM who were characterized by a mean duration of disease of 33 years, suboptimal glucose control with MDI, and frequent hypoglycemic events. Although this study was limited by a very small cohort, after transition to CSII, the mean HbA1c value in this series of five patients, decreased from 9.16% to 7.6% ($p < 0.0025$), and the adjusted frequency of severe hypoglycemia

decreased from 3.2 episodes to 0.4 episodes per year ($p < 0.02$) during an average follow-up of 12.6 months. Given these results, there is reason to suggest a benefit of decreased hypoglycemia in the elderly as was seen in the young.

Additionally, special populations such as the newly diagnosed individual with T1DM have been examined as to their potential benefit from CSII. Ramchandani et al. [23] studied 28 patients with newly diagnosed T1DM, mean age of 12.1 ± 6.2 years initiated on CSII, as early as within 1 day of being diagnosed. All subjects accepted CSII when offered and none elected to discontinue CSII after follow-up periods of up to 3 years — suggesting clear therapy acceptance. Expectedly, HbA1c levels declined from an initial mean of $10.5 \pm 2.4\%$ to between 6.5% and 7.4% over the next 18 months, at a mean insulin requirement of 0.33 units $kg^{-1} d^{-1}$ at 3 months, which by 18 months rose to 0.58 units $kg^{-1} d^{-1}$. C-peptide values remained stable during the first 12 months after diagnosis; but there was no significant weight gain for the duration of the study (20.7 $kg m^{-2}$ vs. a peak of 22.1 $kg m^{-2}$ at 12 months; $p = 0.54$). Indeed, early initiation of pump therapy might better preserve β-cell function than MDI. Thrailkill [24] reported a randomized controlled study in 24 patients, 8–18 years old, with newly diagnosed T1DM, evaluated at enrollment and 1, 3, 6, 9, and 12 months after initial diagnosis of T1DM. Preservation of insulin secretion, measured by mixed-meal–stimulated C-peptide secretion, was compared after 6 and 12 months of treatment. Initiation of pump therapy within 1 month of diagnosis resulted in consistently higher mixed-meal tolerance test–stimulated C-peptide values at all time points, although differences were not statistically significant. Improved glycemic control was observed in insulin pump-treated subjects (more time spent with normoglycemia, better mean HbA1c), and pump-treated subjects reported comparatively greater satisfaction with route of treatment administration.

In pregnancy, although data specific to randomized control studies comparing MDI to CSII are not available, for those women who do use insulin in pregnancy, insulin pumps may facilitate normalized glucose with fewer excursions, fewer hypoglycemic episodes, and better adherence to aggressive insulin regimens than with MDI [25]. It is unclear whether pumps provide tighter glucose control or simply ease the use of insulin by reducing the need to carry syringes and insulin, as well as serving as a reminder to monitor and manage blood glucose. Dosing in 1/20ths of units over long and short intervals with the ability to interrupt or modify post hoc allows precision as well as flexibility. Insulin pumps allow for lower insulin doses and may facilitate the use of U-500 regular insulin in the very insulin-resistant woman, although the considerable risk of hypoglycemia with this insulin should be kept in mind. However, there is little evidence to support that insulin pumps improve glycemic control during pregnancy compared to well-managed MDI insulin use [26]. The prevalence of large for gestational age babies and fetal morbidity were similar between groups randomized to insulin pump versus MDI insulin use [27].

Another systematic review by Jeitler [28] included studies of those with both T1 and T2DM. Although only two papers on CSII in T2DM were included, in the patients with T2DM, CSII and MDI treatment showed no significant difference for HbA1c, in contrast to those with T1DM. Severe hypoglycemia was rare, but a trend toward lower incidence was noted in those on CSII. Mild hypoglycemia was not felt to be statistically different in one study, while only a trend toward lower incidence was shown with CSII in the other study. Hyperglycemia events were reported only in one study, with CSII patients having fewer than the MDI patients, but without statistical analysis as to significance being provided, the outcome is nebulous.

Most recently, yet another systematic review and meta-analysis [29] was designed to compare the effects of CSII with MDI. Using randomized controlled trials (RCTs) among children, adolescents, or adults with either T1 or T2DM, or pregnant women with pre-existing diabetes no difference was observed in the effect of CSII and MDI on HbA1c (moderate strength of evidence) or severe hypoglycemia (low strength of evidence) for adults with T2DM. There was insufficient evidence about quality of life for adults with T2DM.

Although randomized control trials showing comparison effects between MDI and CSII are not available, there is some consensus that supports the consideration of CSII over MDI for diabetic patients with certain needs. Specifically, diabetics with changing work schedules or shifts, athletes that benefit from the ability to suspend insulin delivery, those with significant dawn phenomenon or early morning hyperglycemia, patients with gastroparesis as well as those with variable daytime insulin needs. In short, many recommendations for insulin pump therapy are based on best practice approaches.

Insulin pump use

While patients are best served by the expertise of an endocrinologist working in collaboration with a certified diabetes educator pump trainer in considering insulin pump therapy, many caveats exist which must be explored in order to glean the maximum benefit of a pump over MDI. One factor to assess is patient motivation as only those with a considerable amount of dedication with benefit from insulin pump therapy. A supportive team is also needed to help with education, initiation, and maintenance of support on insulin pump therapy. Members of the team are relied upon to provide the patient with critical tools (carbohydrate counting, correction insulin algorithms, etc.) all along the process to make CSII successful [30].

Supporting the patient in maintaining their motivation is important as is education on how to best use multiple daily injections. Patients must remain open to learning new strategies for diabetes management in order to be truly successful with insulin pump therapy. Like many aspects of diabetes therapy, and especially insulin pump therapy, there are no data to predict "success" (which can be defined differently by different experts);

nevertheless, the need exists for development of some basic steps/skills.

While self-motivation is fundamental to success, without frequent self-monitoring of blood glucose (SMBG) or continuous glucose monitoring (CGM) patients lack necessary information for making adjustments in insulin dosing, food intake, or exercise to decrease glycemic variability. When controlling for frequency of SMBG, there is no advantage for CSII compared to MDI, particularly when there are fewer than four daily blood tests. As the frequency of SMBG increases, there appears an advantage to HbA1c with CSII [31]. While this is simply an observational study and firm conclusions cannot be made, making small insulin changes (often referred to as "fine-tuning" or "micromanaging") with a pump could potentially have a more favorable impact on HbA1c with more frequent SMBG. Most insurance companies are now requesting documentation of at least four daily blood glucose tests to better ensure a good outcome with CSII. In our clinic, we strongly encourage a minimum of four SMBG tests each day before consideration of CSII. The use of routine glucose meter downloading ensures ease of documenting frequency of SMBG, which is either sent to the payer electronically, or printed and faxed.

Discussing realistic expectations and goals of CSII is part of building the foundation for insulin pump therapy. Many patients have an unrealistic expectation that their insulin pump will free them from the demands of self-management and ongoing personal attention to their treatment. We often discuss how the opposite is true and that they will be required to spend even more time and attention on diabetes management. From the Joslin group in Boston, MA, it has been noted that those patients who described the pump as a tool, not a cure, to meet glycemic goals, reported a more active approach to their diabetes and had better glycemic control [32].

Knowing what to do with the glucose data from SMBG or CGM is another key factor [30]. Simply measuring glucose levels each day on a standalone basis is not the same as using the data for action. Part of the controversy as to the benefit of SMBG has been that merely checking fingerstick glucoses is not helpful unless it is used to determine an action [33]. Whether using MDI or CSII, patients are best served by knowing what to do with the SMBG information they generate. Ideally all patients using MDI, but particularly those initiating CSII, should understand the basics of correcting pre-meal or between-meal hyperglycemia (and for that matter, hypoglycemia). This should include routine use of correction dose insulin so that patients understand the concepts of "insulin sensitivity factor" (or correction dose), "insulin on board," and "insulin stacking." Similarly, understanding the risks of overtreating mild hypoglycemia and how to avoid doing so should be a routine aspect of diabetes education. Diabetes educators are the best resource for teaching these basic concepts to either MDI or CSII users; they are an integral part of the treatment team and their role in insulin pump therapy cannot be emphasized enough [30]. While a physician in solo practice certainly can participate

in all aspects of this type of diabetes education, this is not a realistic option for the majority due to the tremendous time commitment.

Additionally, an understanding of matching insulin to food intake is critical to the success of CSII use. On occasion, a patient may do well without understanding the basics of carbohydrate counting, but this is more the exception. Those individuals who are consistent with their food selections on a daily basis, particularly with frequent SMBG, can often maintain reasonable glucose control by frequent "touch-ups" using small amounts of correction dose insulin or food to correct hypoglycemia. Many patients initiating the process toward CSII have not had any diabetes education, particularly nutrition education, for many years. Consequently, their benefit from meeting with a nutritionist prior to starting insulin pump therapy can be significant. With carbohydrate content now listed on food labels and available in many restaurants, the process of carbohydrate counting and determining insulin doses is far easier than it was in the past. Furthermore, there are many sites on the Internet and even "apps" for smart phones and tablets that can assist patients with understanding carbohydrate content of nonlabeled foods.

Some amount of trial and error in prandial insulin dosing is to be expected and yet there are several general points that many patients, as well as clinicians, do not generally appreciate. For example, if a meal contains a significant amount of fiber (>5 g), one half of the fiber portion of the total carbohydrate value should be subtracted from the carbohydrate dose [34]. So for a 40 g carbohydrate meal with 10 g of fiber, the insulin dose should calculated based on 40 g minus $(10 g/2) = 35 g$ of carbohydrate. In general, exercising within 3 hours of a mealtime bolus or injection means the mealtime carbohydrate ratio should be raised (or a fraction of the recommended dose should be administered) to provide a lower dose of insulin. Finally, the timing of the insulin as it relates to when the meal is consumed (the "lag time") is an underemphasized and underappreciated aspect of mealtime insulin dosing that should also be reviewed prior to insulin pump therapy [6,35]. Furthermore, confusion exists among both clinicians and patients about the difference between pharmacokinetics and pharmacodynamics with insulin, especially prandial insulin. Those using continuous glucose sensors quickly appreciate the slowness of action of "fast" insulin, as glucose trends are followed in response to a bolus insulin dose.

Even though there may not be agreement on what constitutes success, trying to manage and educate pump patients without a high level of support often leads to failure. The multidisciplinary "diabetes team," has been shown to significantly improve the successful initiation of CSII therapy [7] but, unfortunately, many patients do not have that option. Diabetes care centers in the United States usually have several components of the traditional diabetes team: nurse educators, nutritionists, and occasionally clinical pharmacists, behavioral scientists (psychologists, psychiatrists), advanced nurse practitioners, social workers, and rarely exercise physiologists. These individuals are often certified diabetes educators (CDEs) and are the nucleus that coordinates the glycemic management in all patients, but particularly those using CSII. Many physicians in smaller, nondiabetes centers have some element of the diabetes team in their office or nearby. It is not realistic for patients using CSII to do as well as possible without some assistance in both the initial education and longer term teaching-management. Many communities have CDEs who are knowledgeable about pump therapy, and they are close by, often within a hospital setting for consultation. Access is typically facilitated through a physician referral to ensure reimbursement. Pump companies can also often provide the initial pump training. Between this one-on-one contact and the company's website, many of the initial training issues can be adequately addressed. However, patient follow-through after the initial training is often inconsistent and so pump management suffers. Pumps offer many advanced features which do not get covered in the initial training so by failing to maintain contact, patients do not reap the full reward of insulin pump therapy such as bolus calculators and temporary basal rates. Finally, much of the initial education can be forgotten if it is not being actively reinforced by the patient's primary diabetes provider. In our experience, the patient's old habits will return and the pump becomes a more frustrating than helpful tool with diabetes management.

Nontraditional options do exist for patients where the physician (or nurse practitioner) does not have access to these other components of the diabetes team. Pump manufacturing companies are endeavoring to fill the gap by providing advanced pump training classes and support groups. Depending on the pump chosen, one may find in-depth training via a sophisticated and interactive website. There are also outstanding reference books and apps for smartphones, with websites for all insulin pump companies that allow for some hands-on experience in managing insulin pumps "virtually." Some even provide a step-by-step introduction of pump use.

Thankfully, the traditional clinic setting is not the only place to gain the much-needed education and training.

Real-time continuous glucose monitoring (RT-CGM) linked to insulin pump

As noted earlier, advances in combining continuous glucose sensing with pump therapy is moving technology toward the ultimate goal of an artificial pancreas. Data have been accumulating on the integrated modalities of RT-CGM and pumps specific to glycemic control, quality of life, and, hopefully in the near future, on diabetes complications prevention. Early studies, such as those of Peyrot et al. [36] focused on both patient acceptance of an integrated system, as well as effects on glycemic control. In this study, 28 patients with T1DM with HbA1c from 7.5–11.1% (average 8.6%) were randomized to MDI and SMBG (control group) or CSII and RT-CGM

(study group) and results reviewed after 4 months. Parameters examined included weight, HbA1c, severe hypoglycemia, and episodes of ketoacidosis. Additionally, a number of satisfaction surveys were completed targeting the integrated system users and user acceptance. Outcome data showed statistically significant decreases in HbA1c from baseline of 1.7% in the study group (8.87 ± 0.89% to 7.16 ± 0.75%; $p \leq 0.001$) versus 1.0% in the controls (8.32 ± 1.05% to 7.30 ± 0.92%; $p \leq 0.002$); however, the difference in change between the two groups (0.7%) was not statistically significant ($p = 0.071$). There were small nonsignificant increases in weight from baseline of 0.7 kg in the study group and 2.0 kg in the controls; the difference in change between groups (1.3 kg) was not significant ($p = 0.309$). There were three severe hypoglycemia events, one incidence of diabetic ketoacidosis, all in the controls. Of more interest, the integrated RT-CGM/insulin pump system was associated with substantial patient-reported benefits over SMBG /MDI. Treatment satisfaction measures, particularly burden of blood glucose monitoring and convenience, as well as measures of health-related quality of life, including social burden and diabetes-related worries were significantly more positive for the integrated system uses. However, there was no difference in measures regarding interference in daily activities and psychological well-being, despite which, the integrated system users were less likely to want to switch away from RT-CGM/CSII and were more likely to recommend it to others.

A larger study by the same group [37] assessed satisfaction between CSII and SMBG versus CSII and RT-CGM. Just over 300 patients with median age 43 years, majority (94%) with T1DM, majority with diabetes duration over 15 years (61%), and median use of insulin use 15 years were queried through an internet survey. The RT-CGM/CSII group gave significantly better ratings than the SMBG + CSII group for their glucose monitoring system's glucose control efficacy, overall satisfaction, desire to switch, and willingness to recommend, and significantly worse ratings for interference with daily activities. The RT-CGM/CSII group gave significantly better ratings than the SMBG + CSII group for their insulin delivery system's convenience and glucose control efficacy, overall satisfaction, desire to switch, and willingness to recommend. These results support patient satisfaction with RT-CGM/CSII.

The JDRF trial [38] provided outcome data regarding combined RT-CGM and CSII use in both children and adults. Three hundred and twenty-two study participants from multiple centers already receiving intensive therapy for T1DM were randomized to a group with RT-CGM or to a control group performing SMBG. HbA1c at baseline ranged from 7–10%, ages ranged from 8 years to over 25 years. The primary outcome was change in the HbA1c at 26 weeks. Although this study included participants who were on MDI, the majority were reported as using CSII, with HbA1c of 8.0% or less, and measuring glucose levels more than five times daily. All three available RT-CGM systems were used in this study.

Results showed a clear impact in decreased HbA1c with use of RT-CGM, irrespective of whether MDI or CSII was used. Results were stratified by age, with the over 25 year olds achieving most significant HbA1c lowering, mean change, −0.53%; 95% CI −0.71 to −0.35; $p < 0.001$). In primary analyses, neither those 15–24 years of age nor those 8–14 years of age had statistical changes in HbA1c. However, the 8–14 year olds started on RT-CGM were more likely to have had a baseline HbA1c of less than 7.0%, and more had a decrease of 10% or more from baseline.

There was also a clear relationship between the frequency of use of RT-CGM and improved HbA1c; furthermore, the group that wore the RT-CGM the least was the age group that did not see an HbA1c impact. Severe hypoglycemic events were infrequent in both study groups, with no significant differences between the groups on the basis of age. This is significant, in that with the HbA1c improvement in the over 25 year olds, there was no associated increase in hypoglycemia—in direct contrast to the DCCT [39] which clearly showed a significant increase in hypoglycemia with lower HbA1c levels.

STAR 3 [40] focused entirely on an integrated RT-GM and CSII protocol in study participants. Over 400 participants from multiple centers were randomly assigned to receive either sensor-augmented pump therapy or a regimen of multiple daily injections, stratified according to age group: adults (19–70 years of age) or children (7–18 years of age), and followed for 1 year. HbA1c was measured, as well as rates of severe hypoglycemia and ketoacidosis. Baseline mean HbA1c in both intervention as well as control groups of 8.3% decreased to 7.5% in the pump-therapy group (absolute reduction, 0.8 ± 0.8 percentage points), as compared with 8.1% in the injection-therapy group (absolute reduction, 0.2 ± 0.9 percentage points), for a between-group difference in the pump-therapy group of −0.6 percentage points. Both age groups benefitted, in the adult group, absolute reduction in the mean HbA1c was 1.0 ± 0.7 percentage points in the pump-therapy group, and 0.4 ± 0.8 percentage points in the injection-therapy group, for a between-group difference in the pump-therapy group of −0.6 percentage points. Among children, an absolute reduction in HbA1c of 0.4 ± 0.9 percentage points in the pump-therapy group but an increase of 0.2 ± 1.0 percentage points in the injection-therapy group, showed a between-group difference favoring the pump-therapy group of −0.5 percentage points.

There was no difference in rates of severe hypoglycemia or ketoacidosis between groups, or by age. Additionally, frequency of sensor use of 41–60% was associated with a reduction of 0.64 percentage points in HbA1c levels, and increasing sensor use to more than 80% doubled the effect. The difference between the JDRF study and STAR 3 trial results specific to use of sensor and associated HbA1c improvement was suggested as attributed to therapy management software used in the latter.

Most recently the combination of a continuous glucose sensor and pump delivery system that has the added capacity for insulin delivery suspension at a preset glucose threshold has advanced

the movement toward an artificial pump. Available in most of the world, but not until 2013 in the United States, this system has been shown to reduce nocturnal hypoglycemia in those at greatest risk and was well accepted by patients [41].

Adding RT-CGM to pump therapy

As with the initiation of insulin pump therapy, RT-CGM initiation requires a motivated patient, discussion of expectations, a team that supports the educational process for successfully using RT-CGM, as well the initiation and management of data stages following the start of RT-CGM. Presently, our clinic prescribes an initial presensor class, then one-on-one initiation, followed by prompt and routinely scheduled appointments to cover ongoing management. As indicated, patients also receive telephone support to provide timely education between appointments. Evert and colleagues from our clinical center [42] have outlined a program for RT-CGM starting with an instructional presentation in class setting, after RT-CGM use is recommended by a clinician to a patient. There is limited data regarding which patients may be best suited for using real-time CGM as a self-management tool. Ritholz and others [32,43] attempted to identify patient groups more likely to benefit from insulin pump initiation. Reportedly, patients with higher A1c values expected the device to improve glycemic control without their active involvement, whereas patients with lower A1c values understood that they were the agents of change and conceptualized the insulin pump as a tool that assisted their self-care. Predictably, active participation in self-care and realistic expectations of the device were associated with better glycemic control. Similarly, it would be expected that the same would hold true for any diabetes technology, and specifically a continuous glucose sensor system. By adding the RT-CGM, you must also add education beyond grasping elements of diabetes knowledge and demonstrating the required skills for pump initiation. Additional understanding is necessary about how the RT-CGM operates and the fact that it relays glucose trends and not absolute values. This point is critical, as patients need to be informed about the likely need to increase SMBG in order to validate true glucose levels when glucose trends show steep rises or declines due to the delay in sensor readings from interstitial fluid reflecting actual glucose levels.

While the structured approach to RT-CGM offered in our clinic has yet to be validated, our center's experience reflects less patient frustration with insertion technique and increased confidence in how to respond to RT-CGM obtained data. We do recommend a two-step process for patients working toward the use of the integrated sensor and pump system: (1) obtain a pump and develop pump-use skills; (2) add the RT-CGM component. Making use of this approach results in very few patients being overwhelmed whereas starting with both components has led to considerable frustration and in some cases outright refusal to persist with either modality. There are always exceptions, when

this process works as well with the sensor first, followed by the pump. Studies as to best approach are clearly needed.

Following the presensor class, at which the various sensors are presented and discussed as to operational details, patients are given contact information should they decide to place an order. Empowered with the option to follow through, the patient is either accepting or declining the addition of a sensor to their pump. As patients obtain the RT-CGM system, they are called with instructions on how to prepare for their scheduled initiation. One requirement is to charge the system transmitter or receiver the night before and review the manufacturer's instruction materials. Educators again play an important role during initiation as they explain how RT-CGM differs from capillary SMBG and reinforce the need for continued SMBG for the ongoing calibration of the system.

In the beginning, patients should be encouraged to note the information from the RT-CGM receiver for 3 to 7 days without taking action in order to reduce the potential for overcorrection in response to alarms. It is important to inform patients that it is very common to become overwhelmed and frustrated by the amount of data and information they will be receiving in "real time" [44]. Another norm with real-time CGM is that patients will be out of target range more than 50% of the time [44]. Informing patients on what to expect will help minimize their frustration and worry while maximizing the effectiveness of the modality. Following-up soon after RT-CGM initiation is sound practice to resolve technical problems such as insertion technique, offer reminders regarding calibration with SMBG, reevaluate settings specific to high and low glucose alarms, and perhaps most importantly, to review. Each patient has a unique learning curve and will need guidance on how to effectively use the data they are seeing to adjust insulin dosing, timing of dosing, meal content or meal amount, or physical activity.

Future trends

Even with all of the technological advances in insulin pumps and their integration with other modalities, barriers to its adoption still exist for patients, besides cost. Improving many features of the external pump could reduce not only treatment constraints, but also improve quality of life. Drawbacks include: initial technical education on how to use the pump and insert the catheter takes time; the negative impression some patients have of being attached to an external device, and common equipment problems, such as catheter occlusion and bent cannula; time-consuming recommendations to disconnect the pump before taking a shower or engaging in water or other sports activities [45]. Upgrades to infusion sets are indicated to achieve the goal of reducing insulin occlusions and unexplained hyperglycemia.

Patch pumps have appealed to some, as they are smaller and lighter than pumps with cannulas and are free of tubing making them more discrete. Patients require less instruction time on

their use and the device is usually simpler in nature than the typical pump thereby reducing technical issues. A few of these pumps are already available for use; others will be in the near future [46]. Some have described the patch pump as an insulin pen that is worn on the body. The basic design comprises an insulin reservoir, delivery system and cannula, all of which are integrated into a small, wearable, disposable or semidisposable device. For some models, insulin delivery can be directed though a separate handheld personal data manager (PDM), for others, insulin is delivered through a preset basal rate, but allowing an on-demand bolus delivery, changed daily. Other models in development allow for the handheld data manager to not only deliver insulin, but contain a glucose meter and food library. Yet another patch pump will increase the reservoir capacity so that refills occur every 6 days with the pump lasting 3 months. Many of these latter pumps are being targeted to the market for T2DM since that population is more suited to the limited basal rate adjustment capacity of the patch pump [45].

Next on the horizon is a closed loop completely integrated insulin delivery and glucose-sensing system. Hypoglycemia sensing remains the major concern for safety in a closed loop system. Alerts for this condition are integrated into RT-CGM systems; however, the DirectNet Study Group [47] showed that 71% of patients—specifically, children and adolescents—did not react to the hypoglycemia alerts that occurred during sleep. This is particularly concerning as most episodes of severe hypoglycemia happen at night [48]. In response, the low-glucose suspend (LGS) system has been developed and is in use. The Veo™ model (marketed in the United States as the Medtronic 530 pump system with Enlight sensor), system uses data transmitted by RT-CGM sensor to automatically suspend the delivery of insulin in cases of hypoglycemia. This "automatic stop" function is activated when the sensor detects interstitial glucose levels below a predetermined level. Clinical experience with the Paradigm Veo™ pump is still limited, and the efficacy of the system in reducing hypoglycemia has only been evaluated in a few recent short-term studies [41,49]. In the Choudhary study [41], hypoglycemia events in those with T1DM, were examined during two consecutive periods. During the first 2-week period, the automatic stop was not activated (LGS was set on OFF). During the consecutive 3 weeks, the LGS was enabled (set on ON). The results showed that patients with a high risk of hypoglycemia significantly reduced their nighttime hypoglycemia duration with no hyperglycemic rebound or ketosis while using the LGS function. Similar results were reported in the Danne study [49] in diabetic children and adolescent subjects. Finally, Garg et al. [50] showed a 19% reduction of hypoglycemic exposure with exercise-induced hypoglycemia.

Reducing hypoglycemia is a central goal in the overall balance of pros and cons to any diabetes therapy. Intraperitoneal delivery of insulin has the advantage of approximating more physiologic insulin action kinetics. Intraperitoneal insulin is absorbed mainly in the portal vein, allowing for lower peripheral insulin levels and even improved glucagon response to hypoglycemia [51]. The use of the intraperitoneal route for T1DM treatment was made possible by the development of programmable implantable pumps that deliver insulin through an intraperitoneal catheter. As an example, the implanted MIP 2007 model (Medtronic-MiniMed, Northridge, CA, USA), was first in use in 2000, having a 7- to 10-year battery life. Insulin delivery options are similar to those of the most up-to-date external pumps, and are programmable through a personal pump communicator (PPC). A patient using a Medtronic implantable insulin pump reported his positive experiences in 2008, offering 8 years of observations of use. With delivery of insulin directly into the peritoneal cavity, he reported feeling better, having more flexibility in eating, and fewer insulin reactions. However, at the conclusion of the article, he expresses disappointment that the manufacturer of the pump, Medtronic, no longer plans to seek Food and Drug Administration approval for this therapy [52].

The metabolic benefits, from observational studies on implantable pumps, show a decrease in HbA1c, a decrease in the frequency of severe hypoglycemia, and even less glycemic variability [45]. These benefits persist over time, even in type 1 diabetics who have not even closely reached HbA1c target of 7% and/or have large blood glucose fluctuations, severe recurrent hypoglycemia, despite tight coaching and intensified education with previous subcutaneous insulin treatment [53]. A Dutch study [54] has shown that, with an implanted insulin pump, not only was HbA1c significantly improved in those who were previously poorly controlled, but instability-related diabetic hospitalizations were also significantly reduced.

However, despite reported improvement in quality of life [46], use of implantable pumps remains limited, essentially pre-scribed only in Europe. The limitations of this treatment mode are the result of its technically specialized medical requirements, significant cost with lack of reimbursement, as well limited manufacturing. With regard to implanted pumps coupled with glucose sensors, the pharmacokinetic properties of intraperi-toneally administered insulin is of particular interest for use in a closed-loop system. Pilot studies have shown encouraging results with implanted pumps coupled with intravenous [55] and more practical subcutaneous glucose sensors [56].

Conclusion

Progress has been both steady and encouraging since Kadish's first pump prototype was unveiled in the 1960s. Safer, smaller, smarter pumps now coupled to continuous glucose sensing have given patients a more comprehensive diabetes management tool that takes advantage of computerized programs for tracking insulin doses and integrating glucose and carbohydrate data to guide patients in improving their care. The resident intelligence of these devices has taken great strides to where they provide suggestions for bolus insulin dosing and even turn themselves

off completely when a low glucose level is perceived. Still, no system is perfect and pumps still occlude, sensors can "break," and the transmission of data between devices can be disrupted thereby causing problems for users. As technology advances the options for diabetes management, providers must also stay in step to ensure that patients feel comfortable embracing those options. In total, the future holds much promise toward continued improvements in a system that will eventually take over the management of glucose and insulin for everyone with diabetes mellitus. A table of current insulin pump models can be found at the end of this article (Table 49.1).

Innovative therapies in diabetes: colesevelam and bromocriptine

Shamsa Ali and Vivian Fonseca

Section of Endocrinology, Tulane University Health Sciences Center, New Orleans, LA, USA

Key points

- There is an ongoing need for development of novel therapies for the treatment of type 2 diabetes mellitus. Two oral agents (colesevelam and bromocriptine) recently became available for the treatment of T2DM.

- Colesevelam is an antihyperlipidemic agent approved by the US FDA for the treatment of T2DM. The ability of colesevelam to lower LDL-cholesterol and hyperglycemia makes it a useful single agent to address both hyperlipidemia and hyperglycemia in patients with T2DM.

- Colesevelam has a good safety profile as it is not absorbed systemically; however, it should be used with caution in patients with hypertriglyceridemia.

- Bromocriptine-QR, a dopamine receptor (D_2) agonist is a first-in-class agent that is FDA approved for the treatment of T2DM. Bromocriptine has a unique mechanism of action that is unlike any other medication currently available for the treatment of T2DM.

- Bromocriptine-QR works centrally by resetting the hypothalamic circadian rhythm and increasing central dopamine activity.

- Bromocriptine-QR is a safe and efficacious treatment for T2DM.

Colesevelam

Colesevelam HCL is a nonsystemic bile acid sequestrant (BAS) approved by the FDA for the treatment of dyslipidemia and T2DM. Treatment with colesevelam is associated with significant reductions not only in LDL-cholesterol (LDL-C) but also in fasting plasma glucose and hemoglobin A1c. Colesevelam is especially beneficial in the management of patients with T2DM and elevated LDL-C. Caution should be observed in patients with hypertriglyceridemia, as treatment with colesevalam is associated with a significant increase in triglyceride levels. Trivial reductions in total cholesterol and high-density lipoprotein (HDL) have been reported.

Mechanism of action

Bile acids are synthesized in the liver, transported to the duodenum, and are essential for digestion as well as absorption of fats in the food. Approximately 90% of the bile acids are reabsorbed in the terminal ileum and enter into enterohepatic circulation. Colesevelam interferes with enterohepatic circulation by binding to the bile acids and forming complexes to be excreted in feces. This causes deficiency in bile acids, which in turn stimulates an increase in the synthesis of bile acids in the liver utilizing cholesterol and thus decreasing the intrahepatic cholesterol concentration. This leads to upregulation of LDL receptors on the liver surface to help preserve hepatic cholesterol balance resulting in increased clearance of LDL from blood leading to decreased serum concentration of LDL and explains the cholesterol-lowering effect of colesevelam as well as other BAS [1].

Mechanism of glycemic improvement

The mechanism by which bile acid sequestrants affect glycemia is unclear. One suggested mechanism of action is through their effect on various nuclear receptors. Farnesoid X receptor (FXR), which is present in both liver and intestines, liver X receptor (LXR), which is present in liver, and a G protein-coupled receptor (TGR-5) present in the intestines are implicated in the regulation of glucose metabolism and also have a crucial role in bile acid and triglyceride homeostasis [2–4].

Bile acids exert a negative feedback effect by activating FXR to prevent build-up of high levels of bile acids in the liver [3]. FXR possibly regulates glucose metabolism via a pathway mediated by fibroblast growth factor 15/19 (FGF15 (mice)/19(humans)). Increased metabolic rate and decreased adiposity have been reported in transgenic mice expressing human FGF19 [5].

Treatment with a bile acid sequestrant in patients with T2DM and hypercholesterolemia has shown a significant increase in GLP-1 levels explaining at least in part the mechanism of glycemic improvement with the use of BAS [6].

Once FXR is activated, it upregulates expression of a small heterodimer protein (SHP) which is an inhibitor of LXR. LXR-induced bile acid synthesis is inactivated by the SHP [3].

Pharmacokinetic and pharmacodynamics

Pharmacokinetic data with all BAS is limited mainly because they are not systemically absorbed [7]. Colesevelam undergoes nonsignificant systemic absorption and also has minimal tissue concentration, volume of distribution, plasma protein binding, and systemic metabolism. It has minimal renal clearance due to negligible systemic absorption and is mostly excreted though feces [8,9]. Colesevelam has a higher potency and its binding affinity is four to six times greater than other BAS [7].

Efficacy of coleselevam
Low-density lipoprotein

Several classes of cholesterol-lowering drugs, namely statins, nicotinic acid, fibrates, cholesterol absorption inhibitors, and BAS are used for treatment of dyslipidemia. It is well known that BAS lower LDL-C [10,11] (Table 50.1). A meta-analysis of pooled data from eight studies reported a statistically significant reduction in LDL associated with colesevelam [12].

Colesevelam can be used as a monotherapy as well as in combination with other lipid-lowering agents. In a double-blind placebo-controlled trial, colesevelam as a monotherapy lowered LDL-C by up to 18% [13] whereas when combined with statin it has been shown to reduce LDL-C by as much as 48% [14].

Hemoglobin A1c

Treatment with colesevelam is associated with a statistically significant reduction in hemoglobin A1c [12] (Table 50.2).

In a short-term double-blind crossover trial, cholestyramine (bile acid sequestrant) was reported not only to improve dyslipidemia but also glucose metabolism [15]. This observation led to the Glucose-Lowering Effect of WelChol Study (GLOWS), which evaluated the glucose-lowering effects of colesevelam HCl in patients with inadequately controlled T2DM [16]. Colesevelam added to an existing metformin and/or sulfonylurea regimen was associated with significant reductions in A1c, fructosamine, and postprandial blood glucose level. Reduction in A1c of up to 1.0% was reported in patients with higher baseline A1c (at least 8%) [16].

In a 26-week, randomized, double-blind, placebo-controlled study colesevelam was added to the regimen of patients with inadequately controlled T2DM who were on metformin alone or metformin combined with other oral agents. The study reported significant lowering of the mean HbA1c level compared with placebo (-0.54%; $p < 0.001$) [17].

Triglycerides

Treatment with colesevelam is associated with a statistically significant increase in triglycerides [12] (Table 50.3). Hence its use is contraindicated in patients with triglyceride levels >500 mg dL^{-1} and a history of triglyceride-induced pancreatitis [18].

High-density lipoprotein and total cholesterol

Colesevelam therapy has been reported to cause a statistically insignificant reduction in HDL and total cholesterol [12].

Safety of colesevelam

The most common side effects are related to the gastrointestinal tract including flatulence, constipation, and dyspepsia. The incidence of constipation was reported to be 8.7–11%. Patients who have preexisting constipation can develop fecal impaction [18].

Hypertriglyceridemia is a known side effect of colesevelam as with other BAS. Increase in serum TG concentrations by a median of 5% has been reported in clinical trials. Lipid parameters should be monitored prior to starting colesevelam [18].

Transient hypoglycemia of mild to moderate severity has been reported when colesevelam HCl in used in combination with metformin, sulfonylureas, or insulin in adults with inadequately controlled T2DM [19].

Colesevelam should be used cautiously in patients with a fat-soluble vitamin deficiency. Animal data suggest the possible development of hemorrhage due to colesevelam-induced

Table 50.3 Triglycerides

C, colesevelam; P, placebo; SD, standard deviation

vitamin K deficiency. To ensure adequate absorption oral vitamin supplements should be taken at least 4 h prior to taking colesevelam [18].

Drug interactions

Drug interactions are not expected with colesevelam as it is not systemically absorbed; however, due to its positive charge it can bind with co-administered drugs in a nonspecific manner reducing their bioavailability.

The structure of colesevelam allows it use for greater bile acid-binding potential in contrast to other BAS, possibly minimizing the potential for drug–drug interactions [20].

Oral contraceptives containing ethinyl estradiol and norethindrone, levothyroxine, and phenytoin are known to interact with colesevelam and should be administered ~4 h before colesevelam [7].

Conclusion

Colesevelam causes significant reductions in hemoglobin A1c, plasma fasting glucose, and LDL-C and hence is useful in the treatment of patients with elevated LDL-C and for suboptimal glycemic control in patients with T2DM. Colesevelam can be used by itself or added to an existing regimen for further management of hyperglycemia and hypercholesterolemia. The dual glucose- and lipid-lowering effect of colesevelam makes it unique and helps achieve both glycemic and lipid goals in patients with T2DM.

Attention should be paid to the baseline triglyceride level, as use of colesevelam is associated with an increase in triglyceride level. Colesevelam is nonsystemic and well tolerated.

Bromocriptine-QR

Bromocriptine-QR can be used by itself or in addition to all other available treatments for T2DM. It is a treatment modality with a novel mechanism of action; although not fully understood, it works centrally by resetting hypothalamic circadian rhythm. It delivers a distinct and short-lived interval of circulating bromocriptine in the morning, increasing central dopamine activity.

Mechanism of action

Bromocriptine-QR mediates its effects on glucose metabolism by not directly acting on specific receptors; instead its effects are mediated by resetting the central nervous system (CNS) sympathetic and dopaminergic tone [21]. Addition of bromocriptine-QR to usual treatment regimens for T2DM has shown improvement in fasting as well as postprandial plasma glucose. It is safe to use and is associated with fewer cardiovascular outcomes. Addition of bromocriptine-QR to the existing treatment plan for T2DM provides a new tactic to address inadequately controlled T2DM.

The idea of using bromocriptine-QR for the treatment of T2DM emerged while studying the metabolism of hibernating animals and migrating birds [21,22]. They alter their metabolism according to the time of the year from insulin-sensitive to insulin-resistant states to survive long periods of food deprivation during winter. During this transition there is an increase in lipolytic activity, fatty acid oxidation, and hepatic gluconeogenesis to spare glucose utilization by peripheral tissues. With the arrival of summer, their metabolism reverts back to an insulin-sensitive state. These seasonal metabolic changes are a function of different neurotransmitters in the suprachiasmatic nuclei (SCN)—the mammalian circadian pacemaker—and in the ventromedial hypothalamus (VMH) [21].

During insulin-resistant states, serotonin and noradrenergic levels and activity are increased in VMH, and during insulin-sensitive states these levels decrease or return to normal in animals undergoing seasonal changes in metabolism [23–27]. On the other hand it has been observed that plasma dopamine levels are low in the insulin-resistant state, while with restoration of insulin sensitivity, dopamine levels normalize [28–30].

Alteration of dopaminergic tone in the hypothalamus in the insulin-resistant state leads to modifications in hypothalamic neural activities, which results in excessive production of glucose by the liver, adipose lipolysis, and insulin resistance particularly in the postprandial period. This alteration in hypothalamic dopaminergic tone promotes an increase in hepatic glucose, free fatty acids and triglycerides production, resulting in insulin resistance [28,30–34]. Plasma prolactin concentration peaks during sleep at night in insulin-sensitive individuals whereas the plasma prolactin level is increased twofold during daytime in insulin-resistant humans [35].

Insulin resistance can be induced by destruction of dopaminergic neurons [33]. Bromocriptine administered peripherally or intracerebroventricularly in insulin-resistant animals has been shown to decrease hepatic glucose production, gluconeogenesis, adipose tissue lipolysis, and improve insulin sensitivity [28,31]. Bromocriptine-QR administered within 2 hours of waking reduces elevated prolactin levels during the day restoring dopaminergic activity, which reduces elevated plasma glucose levels [35–39].

Dosage and pharmacokinetics

Cycloset is the brand name of a quick-release formulation of bromocriptine. It is available in a 0.8 mg tablet given once a day. A starting dose of 0.8 mg should be increased weekly from 1.6 mg up to 4.8 mg (maximum dose) within 30 days [40].

After oral administration, bromocriptine-QR is rapidly absorbed in minutes [35]. Absorption is much faster on an empty stomach (maximum plasma concentration within 60 min) as compared to fed states. Food delays the absorption and maximum plasma concentration is achieved in 120 minutes. Only 5–10% of the drug reaches the systemic circulation as it

undergoes extensive hepatic first-pass metabolism. Ninety percent of the drug is excreted through the biliary system [41–43].

Efficacy

The efficacy and safety of bromocriptine in the treatment of T2DM has been evaluated in several studies, including monotherapy trials, two 24-week trials in which bromocriptine was added to sulfonylurea, and in a 52-week randomized, double-blind, placebo-controlled safety trial in which bromocriptine was added to several antidiabetes treatments including insulin (mean baseline HbA1c 8.3%). Significant improvement in HbA1c was reported in patients receiving bromocriptine as an adjunctive therapy to other oral antidiabetic medication [40,44].

A double-blind, placebo-controlled trial enrolled 17 obese subjects with impaired glucose tolerance; patients were randomized to bromocriptine-QR (1.6–2.4 mg d^{-1}) daily or placebo for 18 weeks. The treatment group demonstrated a significant reduction in weight (6.3 ± 1.5 kg, $p < 0.01$) with a decrease in the area under the serum glucose curve of 46% during an oral glucose tolerance test compared to baseline [36].

In a 16-week, double-blind, placebo-controlled study 22 obese subjects with inadequately controlled T2DM were randomized to receive bromocriptine versus placebo. HbA1c was reduced from 8.7 to 8.1%, and fasting plasma glucose reduced from 190 to 172 mg dL^{-1} in the treatment group. In the placebo group HbA1c increased from 8.5 to 9.1%, and fasting plasma glucose increased from 187 to 223 mg dL^{-1} [45].

In a randomized, double-blind placebo-controlled study, addition of once daily bromocriptine-QR to sulfonylurea in patients with inadequately controlled diabetes led to a decrease in HbA1c by 0.55%, and fasting and postprandial glucose by 23 and 26 mg dL^{-1}, respectively. The study also reported a decrease in fasting triglycerides by 72 mg dL^{-1} and postprandial by 63 mg dL^{-1} [35].

In another double-blind placebo-controlled clinical trial 40 obese patients with T2DM were randomly assigned to either receive bromocriptine-QR (2.5 mg daily) or placebo for 3 months. Improvement in FPG level was reported in the bromocriptine-QR group. Reduction in HbA1c in the treatment group was from 9.9 ± 0.3 to $9.5 \pm 0.2\%$ [46].

Recently a study on efficacy and safety of bromocriptine-QR was carried out in an Indian population. The study enrolled 105 patients and randomized them into three groups; group 1 received only bromocriprine-QR, group 2 received metformin 500 mg twice daily, and group 3 received a combination therapy of bromocriprine-QR plus metformin. The mean reductions in HbA1c at 12 weeks were 0.46%, 0.63%, and 0.74% in groups 1, 2, and 3, respectively. At 12 weeks mean FBS in group 1 was reduced by 16.09 mg dL^{-1} ($p < 0.05$). In group 2 the decrease was 37.36 mg dL^{-1} ($p < 0.05$) at 12 weeks, and in the combination group mean FBS was reduced by 44.31 mg dL^{-1} ($p < 0.05$) [47].

Safety

Side effects with bromocriptine-QR monotherapy are generally mild and transient. The most common side effect with bromocriptine-QR monotherapy is nausea when compared to placebo (26 vs. 5%). Other side effects found in bromocriptine-QR versus placebo were asthenia (15 vs. 8%), dizziness (11 vs. 6%), constipation (11 vs. 4%), and rhinitis (8 vs. 5%) [35].

A large 52-week, randomized, double-blind, multicenter trial of 3095 patients was the first study to assess the overall as well as cardiovascular safety of bromocriptine-QR. Serious side effects were 8.6% versus 9.6% with placebo. Statistically significant reduction in cardiovascular (CV) endpoints defined as a composite of myocardial infarction, stroke, coronary revascularization, and hospitalization for angina or congestive heart failure was reported (bromocriptine vs. placebo 1.8% vs. 3.2%, respectively) [44]. The mechanism of such a reduction in cardiovascular events remains unclear.

Incidence of hypoglycemia with bromocriptine-QR monotherapy is similar to placebo. When added to other antidiabetic agents including insulin, a lack of hypoglycemic adverse effects is observed [35]. Bromocriptine-QR does not increase insulin levels, which seems to be the most likely reason for the lack of increase in incidence of hypoglycemia [39].

Contraindications

Bromocriptine-QR is contraindicated in patients with psychotic disorders as it can exacerbate the underlying disorder, T1DM, and nursing women as it can inhibit lactation. Caution should be observed in patients who are on antihypertensive agents as it can cause orthostatic hypotension. Patients should be assessed for postural hypotension prior to staring treatment with bromocriptine-QR [40,48].

Drug interactions

Bromocriptine-QR is metabolized by the CYPA4 pathway in the liver hence CYPA4 inducers reduce serum concentration of bromocriptine-QR and drugs that inhibit CYP3A4 increase bromocriptine-QR concentration [49].

Caution needs to be observed when medications that are highly protein-bound (e.g. salicylates, sulfonamides, chloramphenicol, and probenecid) are concomitantly used with bromocriptine-QR. Being highly bound to serum proteins, bromocriptine-QR can increase the unbound fraction of these medications. Hence its use may alter the effectiveness of the above-mentioned drugs. Bromocriptine-QR is dopamine agonist and its concomitant use with dopamine receptor antagonists, such as neuroleptics or metoclopramide, can reduce the effectiveness of bromocriptine-QR and vice versa. When bromocriptine-QR is used with ergot-related drugs prescribed in the treatment of migraines, it can cause a worsening of ergot-related side effects such as nausea, vomiting,

and fatigue. Ergot agents should not be used within 6 hours of bromocriptine-QR [40,48].

Conclusion

Bromocriptine-QR is not only efficacious in improving glycemia but also has a good safety profile. It does not increase the risk of cardiovascular disease and meets the FDA's new cardiovascular safety guidelines. More studies are needed to elucidate the mechanism of action and biochemical effects of this new, centrally acting medication for treatment of T2DM. Furthermore, longer duration studies should be undertaken to validate cardiovascular safety of bromocriptine-QR. One year may be too short a time to assess cardiovascular safety.

Management of diabetes: monitoring and other interventions

Implantable pumps and artificial and bio-artificial pancreas system

William V. Tamborlane and Miladys M. Palau-Collazo

Department of Pediatrics, Yale University School of Medicine, New Haven, CT, USA

Key points

- Near-normoglycemia and A1c levels should be achieved and maintained early in the course of the disease, preferably since its diagnosis to decrease the risk of complications. However, too many patients with type 1 diabetes (T1DM) fail to achieve target A1c levels with current open-loop therapy.
- All three components for an external closed loop (CL) artificial pancreas system are already available.
- The feasibility of the CL artificial pancreas has been documented in adults, children, and pregnant women who have demonstrated an increased time spent in target range.
- Given the risk from immunosuppressive therapy from islet cell transplantation outweighs the benefits, the most promising therapy for β-cell replacement in patients with T1DM is a fully automated, CL artificial pancreas.
- Bio-artificial pancreas (BAP) is another promising therapeutic approach to transform the treatment of T1DM.

Introduction

Type 1 diabetes (T1DM) is characterized by a progressive decline in insulin secretion leading to absolute insulin deficiency [1]. The incidence of T1DM is rising with an expected doubling in the number of new cases between 2005 and 2020 in children less than the age of 5 [2]. In the 1980s, major advances were made in the treatment and management of T1DM that initiated the start of the intensive treatment era. The Diabetes Control and Complications Trial (DCCT) was a groundbreaking trial conducted between 1983 and 1993 which conclusively demonstrated that intensive therapy (multiple dose injections of insulin a day or insulin pump therapy) with intensive monitoring compared to standard therapy (two injections of insulin a day) with minimal monitoring was more effective in delaying the onset and slowing the progression of

diabetic retinopathy, nephropathy, and neuropathy in patients with T1DM [3]. In the observational study that followed the DCCT, the Epidemiology of Diabetes Interventions and Complications (EDIC) study, the differences in complication development between conventionally treated and intensively treated patients continued to increase despite similar glycemic control during EDIC, a phenomenon referred to as metabolic memory. This observation highlighted the importance of introducing intensive therapy with the aim of glycemic goals as close to normal as possible early in the course of the disease [4].

In order to duplicate the physiologic secretion of insulin by the β cell, major advances in human insulin analogue development, with improved pharmacokinetics, have been achieved coupled with significant advances in delivery systems. In 1964, the idea of developing an artificial pancreas (AP) was conceived by Dr. Arnold Kadish and in 1977, the Biostator, the first experimental closed loop (CL) artificial pancreas, became a reality [5]. This device was very useful in the context of short-term experimental studies but was not suitable for home or portable use due to its large size and the requirement of two intravenous catheters; one to measure blood glucose (BG) and another to infuse insulin and glucose [6,7]. The development of continuous subcutaneous insulin infusion (CSII) with a miniature pump in the 1970s and intraperitoneal insulin (IP) delivery with implantable pumps 20 years later overcame one obstacle to the development of a practically applicable closed-loop system. However, a major obstacle to an artificial pancreas remains, and is being addressed with, the introduction of real-time continuous glucose monitoring devices more than 10 years ago [8,9].

Despite advances in open-loop therapy, most patients with T1DM are still being treated with multiple dose injections (MDI) therapy and most people with T1DM do not meet glycemic goals (A1c < 7%) [10]. Moreover, patients who are able to achieve target BG and A1c levels are at higher risk for severe hypoglycemic events, as well as being frequently exposed to asymptomatic

hypoglycemia, especially during the night [3]. Even under the best of circumstances, the constant demands that patients with T1DM have to implement in order to adequately manage their disease can be overwhelming. Only when the patient can be taken out of the equation and when metabolic control can be maintained with little or no effort, will we have achieved the full potential of recent advances in diabetes technology.

The artificial pancreas

Implanted closed-loop system

An early direction of CL development was based on the assumption that a fully implanted system was the "Holy Grail" of this research and the introduction of the MiniMed MIP 2007 implantable insulin pump was one of the first milestones. This pump is a disk shape infusion system implanted in the abdominal wall with the catheter inserted in the peritoneal cavity. It was refilled every 45 to 90 days with a special insulin preparation of human regular insulin stabilized by a surfactant material at a concentration of $400\,IU\,mL^{-1}$ [11–17].

Most of the experience with implantable pumps in open-loop therapy came from the 15 centers that form the EVADIAC association (Evaluation dans le Diabète du Traitement par Implants Actifs) in France. The primary indication for enrollment of patients in implanted pump trials was a failure of intensive insulin treatment using CSII to control hyperglycemia in spite of reinforced patient education and close medical follow-up. Other indications were achievement of target A1c < 7% levels at the expense of recurrent severe hypoglycemia and poor diabetes-related quality of life [12,15]. A summary of the early clinical trials of patients with T1DM treated with implantable insulin pumps can be found in Table 51.1.

Despite the potential benefits of implanted pumps, there is no current research being undertaken to develop new and improved implanted pump systems. Insulin under-delivery due to clogging of the pumping mechanism and peritoneal catheter due to insulin aggregation has been a major problem. Localized site problems or pump pocket events (hematomas, skin erosions, pocket infections, pump migrations, local abdominal pain), pump failures (electrical or mechanical failure, premature battery depletion), and clinical complications (ketoacidosis and severe hypoglycemia) are other issues that may require a surgical operation to replace the pump. Even the regular refills of the pump's reservoir can be challenging [18–22].

It was also believed that optimal performance of a CL artificial pancreas system would require a continuous glucose monitoring system with intravascular implantation of the glucose sensor. While MiniMed reported some encouraging early results with their intravascular sensor that was placed in the superior vena cava, technical and clinical problems have been difficult to overcome [23]. Consequently, no long-term implantable sensor is currently available.

External closed-loop system

In contrast to the difficulties in developing an implantable CL system, all three components for an external system are currently available: transcutaneous continuous glucose sensors that measure interstitial glucose concentrations, external insulin pumps and computer algorithms that determine the amount and rate of insulin delivery based on glucose sensor outputs. In order to achieve the ultimate goal of an outpatient therapy with a fully automated artificial pancreas, the system has to be easily managed by the patient, have safety checks in place to avoid over-delivery of insulin, and be able to respond to the normal daily activities that affect blood sugars levels [10,24].

Table 51.1 Clinical trials of intraperitoneal insulin delivery with implantable insulin pump in patients with type 1 diabetes

Year published (Reference)	Number of patients	Length of study (patient-years)	Mean HbA1c (%) ±SD		Episodes of diabetes ketoacidosis	Severe hypoglycemia (episodes/patient-yr)	
			Initial	Final		Baseline	After
1988 [16]	20	18.2	$7.6 \pm NA$ $p < 0.05$	$7.0 \pm NA$	NA	NA	0.22
1989 [17]	18	28	9.2 ± 0.4 $p < 0.01$	8.2 ± 0.4	None	NA	0.0

Continuous glucose monitoring (CGM) devices

Currently available subcutaneous glucose sensors measure interstitial glucose levels using glucose-oxidase based electrochemical methods. The kinetics between glucose in the blood and interstitium are still not fully elucidated but there are well-documented physiologic lag times between changes in glucose levels in the blood and in the interstitium [26]. Interstitial fluid glucose generates an electrical current when it is oxidized in a reaction catalyzed by glucose oxidase [8]. Electrical current data are transmitted to a receiver and then converted into a glucose level that can be measured in mg dL^{-1} or mmol L^{-1} [25,26]. Boyne et al. (2003) found that time differences between changes in blood and interstitial glucose ranged from 4 to 10 min, with the interstitial glucose lagging behind changes in BG levels [26]. An attached transmitter sends the glucose reading every 1 to 5 min to a receiver with a display screen that is either built into an external insulin pump or a separate device [8]. It has alarms and direction arrows that alert the patient about rapid changes in glucose in either direction (rapid drop or increase in blood sugar). The sensors can be used for as long as 7 days and sensor readings need to be calibrated with BG usually twice a day [10].

Hypoglycemia is one of the main factors limiting the management of T1DM and it may be a life-threatening complication of intensive therapy. The DCCT reported a threefold increase in severe hypoglycemia in those treated with intensive therapy [3,27]. The risk of hypoglycemia is higher in children and adolescents, and increases with the duration of illness or with tight diabetes control (hypoglycemia-associated autonomic failure) [28,29]. Postprandial BG levels are also suboptimal in most patients with T1DM and contribute to an elevated HbA1c and wide BG excursions may be implicated in the pathogenesis of diabetes complications [30]. The introduction of continuous glucose monitoring (CGM) systems has allowed clinicians and patients to have a real-time view of their BG and its use has been associated with improvement in glycemic control if the devices are used frequently enough [31–33].

A number of studies have evaluated the efficacy of CGM with current approaches to open-loop insulin delivery. While CGM has not eliminated the risk of severe hypoglycemia, CGM allows patients to reduce elevated HbA1c levels without increasing the risk of severe hypoglycemia [31]. The benefits of CGM are related to the amount of time they are worn by the patient (on average more than 5 days a week) [31,33]. In a multicenter clinical trial funded by the Juvenile Diabetes Research Foundation (JDRF) an improvement in A1c of 0.5% after 6 months of CGM use was seen in those patients above the age of 25 (83% of patients used the CGM 6 or more days a week) [34]. No significant difference in A1c was noted in the younger group (only 30% of patients age 15–24 and 50% of patients age 8–14 used the CGM on average for 6 or more days) [34]. In well-controlled patients, CGM can substantially reduce exposure to biochemical hypoglycemia, while helping to maintain HbA1c levels within the normal range [34].

Although improvements in accuracy and precision have been achieved with CGM devices, they remain difficult to use on a daily basis by most T1DM patients, especially adolescents and young adults. More frequent use of CGM would result if patients were able to gain a greater benefit from wearing these devices.

Insulin pump

Intensive management of T1DM, with the goal of reaching HbA1c targets of less than 7%, can be done with continuous insulin infusion or with multiple daily injections (MDI). In contrast to MDI, where the patient has to mentally calculate the amount of insulin that is needed to cover carbohydrates or correct a high blood sugar, today's "smart pumps" contain microcomputers that allow preprogramming of different basal rates; calculate the amount of insulin needed for carbohydrate coverage; and calculate correction doses to bring high BG level back in to range and automatically adjust this estimate based on the time since the last correction bolus. They also have the advantage of giving as little as 0.025 units of insulin at a time [35].

The Sensor-Augmented Pump Therapy for A1c Reduction (STAR 3) trial compared the efficacy of Medtronic's MiniMed Paradigm® REAL-Time system with MDI during a 12-month period [33]. Patients on sensor-augmented insulin pump (SAP) therapy demonstrated a reduction in mean A1c levels that was four times greater than the MDI group (0.8% study vs. 0.2% control ($p < 0.001$) and the proportion of patients who reached the HbA1c target (<7%) was greater. The rate of severe hypoglycemia did not differ significantly between the groups. In the continuation phase of the STAR 3 trial, MDI subjects were allowed to switch to SAP therapy for 6 months (the crossover group) and SAP subjects were allowed to remain on uninterrupted SAP therapy for a total of 18 months. A1c values were initially lower in the continuing SAP group than in the crossover group (7.4 vs. 8.0%, $p < 0.001$). There was a statistically significant further A1c reduction in the crossover group after 3 months on the SAP system [32,33]. The improved A1c levels achieved by the SAP group during the first 12 months of the study were maintained at 15 and 18 months. As demonstrated in other studies, sensor wear times of greater than 40% were required to achieve and maintain the metabolic benefits of SAP therapy [33].

Algorithms

Variations of two main control algorithms are currently being used in most of the artificial pancreas clinical trials: the proportional-integral-derivative (PID) algorithm and the model predictive control (MPC) algorithm. The PID algorithm is based on retrospective analysis of prior changes in sensor glucose levels over a fixed period of time (e.g. the last 10 minutes). The insulin delivery calculated on the proportional component is based on how far the actual glucose level is from the desired glucose level; the derivative component varies the rate of insulin delivery based on the rate and direction of change of sensor glucose levels and the integral component is based on

the amount of time BG has remained above or below the target range [10]. PID algorithms essentially look retrospectively to glucose changes over time [24]. The PID algorithm now has an insulin feedback component that takes into account the "insulin-on-board" to avoid late postprandial hypoglycemia that results from delays in absorption of meal-related insulin delivery [24]. MPC algorithms compare the predicted BG with the actual glucose, and then try to predict how much insulin is needed to maintain the blood sugar within a target.

Feasibility studies

The feasibility of the CL artificial pancreas has been documented in adults, children, and pregnant women who have demonstrated an increased time spent in target range. Since CL insulin delivery has reduced but not eliminated problems with hypoglycemia the group from Boston University has developed a bi-hormonal CL artificial pancreas using glucagon as the counterregulatory component.

Even under CL conditions, meal-related BG excursions frequently exceed target levels. This is primarily due to delays in absorption of insulin from the subcutaneous tissue and because the algorithm extends the meal "bolus" over a period of 2–3 hours. The Yale Ultra-Fast Acting Insulin Project was undertaken to explore ways to accelerate the time action profiles of rapid-acting insulin analogues to improve performance of closed and open-loop insulin delivery. Cengiz et al. (2013) have reported that warming the skin around the insulin infusion site to 38.5 °C with the InsuPatch ($IP_{38.5}$) results in an earlier time to peak insulin action (T_{GIRmax}) as compared to control glucose clamps without IP activation (No IP) [36]. Weinzimer and colleagues demonstrated that postprandial hyperglycemia can also be ameliorated by "meal announcement"; namely having the patient administer a partial, pre-meal priming bolus. In their study, this hybrid, semiautomatic approach led to an earlier rise in plasma insulin levels and a reduction in peak postprandial glucose levels [37]. Although this approach did decrease postprandial hyperglycemia, it requires manual inputs from the patient, and it is therefore not fully autonomous [37].

Another strategy for reducing post-meal hyperglycemia is by administration of pre-meal injections of pramlintide. Pramlintide is an analogue of the naturally occurring β-cell peptide amylin. It works by delaying gastric emptying, thus slowing carbohydrate appearance, and by lowering meal-stimulated increases in plasma glucagon levels [38]. This mechanism of action is important given that it is now known that there is a dysregulation of α-cell function even during the very early stages of T1DM. Recently, Sherr et al. (2013) demonstrated that glucagon responses to hypoglycemia were lost in many patients with T1DM during the first 2 years of the disease; whereas, during mixed meal tolerance testing (MMTT), increases in plasma glucagon were greater in T1DM than in non-T1DM subjects. These data suggest that early dysregulation of α-cell function contributes to increasing problems with hyper-, as well as hypoglycemia in patients with T1DM [39]. To improve the

CL control, Weinzimer and his associates studied eight subjects for 48 h on a CL insulin-delivery system with a PID algorithm with insulin feedback: 24 h on CL control alone (CL) and 24 h on CL control plus 30 mg pre-meal injections of pramlintide (CLP) and no pre-meal manual boluses were given. CLP was associated with overall delayed time to peak BG (2.5 ± 0.9 vs. 1.5 ± 0.5 h; $p < 0.0001$) and reduced magnitude of glycemic excursion (88 ± 42 vs. 113 ± 32 mg dL^{-1}; $p = 0.006$) compared with CL alone [38].

The major obstacle to outpatient treatment of T1DM patients is that a number of redundant safeguards must be in place to ensure that no patient is injured by over-delivery of insulin due to a system malfunction. The translation of advances in diabetes technology in CL control into clinical practice will be facilitated by improvement in system hardware and software, some of which are shown in Table 51.2.

While the main danger of CL control is when the system is prompted to increase insulin delivery in response to increasing sensor glucose levels, there are few concerns regarding the safety of shutting down insulin delivery for relatively brief periods of time in response to low sensor glucose levels. The first step in this direction has been achieved with the introduction of the Medtronic's integrated sensor-augmented pump system, which automatically suspends a pump's basal insulin infusion for 2 h if sensor glucose levels fall to a preprogrammed threshold level and the patient does not respond to the alarm. In various studies, it has shown to be safe and effective in reducing the amount of time spent in hypoglycemia and reducing nocturnal hypoglycemia [40,41]. Another recent study demonstrated that a 2-hour period of suspension is safe and does not result in ketoacidosis [42].

As previously described, the artificial pancreas has been tested extensively in the hospital in-patient setting under artificial research conditions that do not represent the day-to-day life of our patients. The first outpatient artificial pancreas study used a smartphone computational platform [43] and a number of similar studies have been launched or completed.

Given that currently the risk from immunosuppressive therapy from islet cell transplantation outweighs the benefits, the most promising therapy for β-cell replacement in patients with T1DM is a fully automated, CL artificial pancreas. Given that all three components for the CL are available, the National Institute of Health, the Juvenile Diabetes Research Foundation,

Table 51.2 Safeguards needed to mitigate the risk of over delivery of insulin by CL systems

- Better and more accurate sensors
- Dual sensors
- Integrity of RF transmissions
- Preventing computer malfunctions
- Limiting maximal delivery rates
- Improved algorithms to detect failing sensors
- Minimizing the risk of user error

and the industry have constructed partnerships to make this dream a reality.

Future directions: bio-artificial pancreas

Bio-artificial pancreas (BAP) systems are devices that contain functional islet cells or bio-engineered β cells. This is an exciting area of research, since development of a bio-artificial pancreas should allow the use of not only allotransplantation but also xenotransplantation of the islets with little or no immunosuppression [44].

The concept of the BAP is to develop an artificial membrane that is permeable to both glucose and insulin and not to the immune system [45,46]. In order to be an acceptable therapy, the BAP should maintain viability and functionality for a prolonged period of time and be easily retrievable or biodegradable [47]. There are different types of membranes and they vary by their geometry and other characteristics. Currently, the three different types of devices that are used are: intravascular, diffusion chambers, and extravascular devices.

The design that most closely mimics the physiologic environment of the islets is the intravascular device. In intravascular devices, islets are encapsulated within one or several hollow biocompatible membrane tubes or fibers and then implanted into the circulatory system via connection to a vascular shunt (artery to vein). Due to direct access to oxygen and nutrients from the blood, islet cell viability and function are maintained and the delay in response to a glucose peak is reduced due to higher diffusion potential [46]. In 2006, Ikeda et al. developed a BAP of this type and were able to achieve normoglycemia in a pancreatectomized pig [48]. Major problems encountered with this device are surgical implantation and clot formation [46].

In a diffusion chamber BAP module, islets are contained between two semipermeable membranes placed on both sides of a ring-like structure that is implanted in the abdominal cavity. This approach has not been successful. The peritoneal implantation results in poor diffusion between the islets and the surrounding blood. Also, the islets tend to clump with each other and undergo necrosis. Furthermore, the mechanical stress from the small intestine peristalsis can destroy these types of chambers [45]. Edamura et al. (2003) used a diffusion chamber module and performed the xenotransplantation of porcine pancreatic endocrine cells to total pancreatectomized dogs. In this experiment, two of the BAPs were completely destroyed, and the remaining one was encapsulated by thin fibrous tissue. On histologic examination on the BAP removed from this dog, necrosis of the pancreatic endocrine cells was observed [49].

Extravascular BAP models can be classified by the size of the device: macrocapsular or microcapsular [46]. Microcapsular devices consist of islets suspended in a polymeric gel material, encapsulated in a biocompatible synthetic membrane. They have been implanted in the peritoneal cavity, the kidney capsule, or subcutaneous tissue. The large surface area allows for substance exchange but once implanted in the body (abdominal cavity), they are not retrievable [44–46]. Living Cell Technologies (LCT) is the first company to enter clinical trials using microspheres containing live porcine islet cells. They developed the product Diabecell® which is implanted into a patient's abdomen using a laparoscopic approach and patients do not require immunosuppression. Clinical trials began in Russia in 2007 at the Sklifosovsky Research Institute in Moscow. Eight patients with insulin-dependent diabetes received between one and three implants of Diabecell. Having completed a successful phase I/IIa clinical trial in Russia, LCT currently has phase IIb clinical trials in New Zealand and Argentina [45].

Macrocapsular devices can be handled macroscopically. They enclose the islets in a larger hydrogel. The advantages are: smaller surgical implantation risk, easier retrievability, size flexibility, and possibly device re-seeding. Their major drawbacks are limited diffusion of nutrients, slow exchange of glucose and insulin, fibrotic response to the outer wall of the membrane, and loss of physical integrity of the capsule. In animal models, a major reason why BAP has failed is due to the development of a fibrotic and inflammatory response to the chemical surface composition of the device [44–46].

The BAP is a promising therapeutic approach for T1DM. Clinical trials of microencapsulated porcine cells are already on their way [45]. Also, recent advances in pancreatic organogenesis has led to the creation of cells with β-cell-like function which could potentially be used in the development of cellular therapy for the treatment of T1DM.

Pancreas and islet transplantation

R. Paul Robertson

Pacific Northwest Diabetes Research Institute; and the University of Washington, Seattle, WA, USA

Key points

- Pancreas transplantation is very effective in providing normal β- and α-cell function and normoglycemia for type 1 diabetic patients.
- Pancreas transplantation arrests and in some cases reverses complications of diabetes, including kidney, eye, nerve, and macrovascular diseases, and improves quality of life in type 1 diabetic recipients.
- Intrahepatic autoislet transplantation is very effective in providing normal β-cell, but not complete α-cell, function after total pancreatectomy for chronic, painful pancreatitis.
- Total pancreatectomy and autoislet transplantation is very effective in relieving abdominal pain, weight loss, and narcotic usage, and improves quality of life in patients with chronic pancreatitis.
- Alloislet transplantaton is somewhat effective in providing normal β-cell, but not complete α-cell, function and a return to normoglycemia with freedom from exogenous insulin.
- Alloislet transplantation is highly effective in preventing hypoglycemia secondary to insulin treatment.

Role of pancreas and islet transplantation in management of diabetes

Pancreas and islet transplantation are normally performed in tertiary care centers that have an active kidney transplant program and that are equipped to handle the complex medical and psychosocial needs of transplant patients. To answer the difficult question of which patient should be recommended for pancreas or islet transplantation, the American Diabetes Association prepared a position statement in 2000 [1]. These recommendations were:

1 Pancreas transplantation should be considered an acceptable therapeutic alternative to continued insulin therapy in diabetic patients with imminent or established end-stage renal disease who have had or plan to have a kidney transplant, because the

successful addition of a pancreas does not jeopardize patient survival, may improve kidney survival, and will restore normal glycemia. Such patients also must meet the medical indications and criteria for kidney transplantation and not have excessive surgical risk for the dual transplant procedure. Medicare and other third-party payers of medical care should include coverage for pancreas transplant procedures meeting these criteria. The pancreas transplant may be done simultaneous with, or subsequent to, a kidney transplant. Pancreas graft survival is better when done simultaneously with a kidney transplant.

2 In the absence of indications for kidney transplantation, pancreas transplantation should only be considered a therapy in patients who exhibit these three criteria: 1) A history of frequent, acute, and severe metabolic complications (hypoglycemia, hyperglycemia, ketoacidosis) requiring medical attention; 2) Clinical and emotional problems with exogenous insulin therapy that are so severe as to be incapacitating; 3) Consistent failure of insulin-based management to prevent acute complications. Program guidelines for insuring an objective multidisciplinary evaluation of the patient's condition and eligibility for transplantation should be established and followed. Third-party payer coverage is appropriate only where such guidelines and procedures exist.

3 Pancreatic islet cell transplants hold significant potential advantages over whole-gland transplants. However, at this time, islet cell transplantation is an experimental procedure, also requiring systemic immunosuppression, and should be performed only within the setting of controlled research studies.

These carefully worded guidelines clearly indicate that pancreas and islet transplantation should not be considered routine care for patients with T1DM. Rather, these procedures are reserved for individuals who are unable to establish control of their glucose levels and/or to have a reasonable quality of life by using conventional nonsurgical measures. The availability of home glucose monitors, multiple preparations of insulin, and new drugs have facilitated the evolution of highly sophisticated therapeutic paradigms so that the majority of type 1 diabetic patients are able to maintain hemoglobin A1c levels that fall within the recommended range. A small number of type 2

diabetic patients have received pancreas transplants, but this is not normally considered to be an option for such patients.

The pancreas transplantation procedure

Pancreas transplantation was first begun for the treatment of T1DM in humans in 1966 [2]. Not many procedures were performed up to 1978 because of the low rates of graft survival. Thereafter, important improvements in immunosuppressive therapy developed, most notably the use of anti-T-cell agents and cyclosporine. These new drugs, combined with new surgical techniques and the selection of healthier recipients, led to a much greater use of pancreas transplant for therapeutic intervention.

Typically, an intact pancreas donated by a person who has died is placed into the pelvis of the recipient whose native pancreas is left untouched. Most grafts receive arterial blood from, and return venous blood to, iliac vessels. Less often hepatic portal venous drainage of the allograft is used [3]. Uncommonly, a hemi-pancreas is donated to a sibling by a healthy, living, related donor who has undergone hemipancreatectomy. When a cadaveric organ is used, a small portion of the donor duodenum containing the exit of the pancreatic duct is included and oversewn onto the urinary bladder. In this manner, the exocrine drainage of the donated organ drains into the bladder and is excreted. Alternatively, enteric rather than bladder drainage is used. Advantages of bladder over enteric drainage are the use of urinary amylase to monitor for rejection of the pancreas and the avoidance of small bowel complications such as obstruction and infection. On the other hand, the advantages of enteric over bladder drainage are the avoidance of urinary bladder infection, hematuria, and reflux pancreatitis. In terms of hepatic portal venous drainage, one advantage is the avoidance of hyperinsulinemia that is caused when systemic venous drainage is used [4]. This arrangement eliminates first pass hepatic metabolism of insulin, which normally is approximately 80–90%. It should also be appreciated that because of its ectopic position, it is highly unlikely that the central nervous system establishes physiologically meaningful innervation of the transplanted organ. This is an important consideration since the central nervous system under normal physiologic conditions is considered to be an important regulator of pancreatic islet function.

Transplanted pancreases can undergo both acute and chronic rejection episodes despite the use of immunosuppressive drugs. Management involves hospitalization and intensification of immunosuppression. If the pancreas is transplanted simultaneously with a kidney, detection of rejection is facilitated because an increase in serum creatinine can be easily monitored and used as a signal that both organs are at risk for undergoing a rejection episode. When a pancreas is transplanted with bladder drainage without a kidney, the less sensitive and later indices of decreasing urinary amylase, increasing serum amylase, and increasing blood glucose levels are the only available warnings

of rejection. Cystoscopic transduodenal or percutaneous biopsy with ultrasound guidance is used to confirm rejection. A renewed autoimmune attack on the transplanted islet has been suggested as a possible cause of graft demise, but this is probably an unusual event, partly because the recipient receives immunosuppressive drugs that are known to suppress primary autoimmune responses.

Conventionally, long-term maintenance of immunosuppression is provided by triple-drug therapy with either cyclosporine or tacrolimus (both calcineurin inhibitors), azathioprine or mycophenolate mofetil (both antimetabolites), and corticosteroids. Increasingly, more immunosuppressive protocols are excluding corticosteroids because of their severe adverse side effects that greatly compromise quality of life, such as metabolic bone disease and cushingnoid appearance. Newer drugs are becoming more increasingly in vogue [5,6].

Serious adverse effects often accompany the surgery required for pancreas transplantation as well as the immunosuppressive drugs used [7]. Perioperative complications leading to laparotomy occur in as many as one of three recipients because of intra-abdominal infections and abscess, vascular graft thrombosis, anastomotic leakage, and duodenal stump leak. Drug-related complications include bacterial and viral infections (particularly cytomegalovirus) and malignancy (particularly skin tumors and lymphoma). Adverse metabolic side effects of the drugs include osteoporosis and insulin resistance as a consequence of using glucocorticoids and decreased renal function as a consequence of using calcineurin inhibitors. Ironically, many of the immunosuppressive drugs, particularly the calcineurin inhibitors and glucocorticoids, have deleterious effects on pancreatic β-cell function. These include decreased β-cell insulin gene expression and insulin content as well as defective insulin secretion in response to glucose [8]. For this reason, newer drugs are being sought that do not adversely affect β-cell function of the transplanted pancreas and do not cause metabolic bone disease.

The islet transplantation procedure

Both autoislet and alloislet transplantation usually have used the intrahepatic site for infusion of islets through a catheter. In the autoislet scenario, a patient with chronic, unrelentingly painful pancreatitis undergoes total pancreatectomy for pain relief. The pancreas is used for islet isolation and the islets are returned via the hepatic portal venous system within 2–4 hours while the patient is still in the operating room. Historically, autoislets were not purified; although more recently some centers favor purification to decrease the mass of tissue infused into the portal circulation because of concerns about increased portal blood pressure. Purification, however, considerably decreases the mass of viable islets eventually infused [9]. The alloislet scenario involves patients with T1DM who typically have significant clinical problems with hypoglycemia secondary

to use of exogenous insulin. Success for alloislet procedure is highly dependent on the total mass of islets transplanted. Usually two separate pancreas donors on two separate occasions are needed to attain freedom from exogenous insulin treatment. Another major difference between the two procedures is that autoislet transplantation does not require immunosuppression, whereas alloiset transplantation does. The approach to immunosuppression is very similar to that used for whole pancreas transplantation. The contrast in the amount of islets required for autoislet and alloislet transplantation is of great interest and points to the likelihood of greater islet damage in the alloislet procedure, possibly because of extensive purification [9], β-cell toxicity of immunosuppressive drugs [8], or recurrence of autoimmune disease. Concern has been expressed about using the liver as the sole transplant site for islets from several points of view [8–12]. The list of complications is substantially different from whole organ transplantation. The problems encountered for autoislet transplants are not intrinsic to intrahepatic islet infusion but rather the surgery involved in total pancreatectomy, which carries the type of risks associated with any major intra-abdominal surgery. On the other hand, alloislet transplantation carries unique risks of bleeding and thrombosis because of the use of a percutaneous metal cannula which is inserted into the liver to advance polyethylene tubing into the hepatic portal venous circulation [13,14]. Very few deaths have been associated with autoislet or alloislet transplantation.

Success rates for pancreas and islet transplantation

Pancreas

Annual pancreas transplantation rates as well as the success rates for patient and organ survivals have continually increased since 1978. By the year 2011 over 18,000 pancreas transplantations had been performed nationally [15,16] (Figure 52.1). Between the years 1978 and 2011 there were many changes in surgical techniques and immunosuppressive drugs that led to progressively higher patient and graft survival rates. Historically, the majority of pancreases were transplanted simultaneously with kidneys. In 1999, of 1287 pancreas transplants reported, 75% were performed simultaneously with kidneys, 18% were performed after kidney transplantation, and 7% were performed unrelated to previous or concurrent kidney transplantation [3]. The patient survival rate for simultaneous pancreas and kidney transplantation 1 year post-transplant is currently 95% [15,16]. It seems likely that the 5% mortality is due more to the chronic diabetic state than the surgery itself because the vast majority of deaths do not occur in the perioperative period and are usually cardiovascular in nature. In this regard, it is important to bear in mind that the average recipient of a pancreas transplant has had diabetes mellitus for over 20 years prior to the surgery and has had serious complications including macrovascular and microvascular disease. For pancreases transplanted simultaneously with kidneys, the pancreas graft survival rate was 79% at 1 year and
Figure 52.1 Patient and pancreas graft survival 1 and 3 years posttransplantation according to the International Pancreas Transplant Registry. Source: Gruessner 2000 [15]. Reproduced with permission of John Wiley.

77% at 3 years. Pancreas transplantation after a previous kidney transplantation rates were 69% at 1 year and 59% at 3 years. Pancreas transplanted alone rates were 65% at 1 year and 58% at 3 years. More recently, in the 2009–2111 era, pancreas survival after a simultaneous pancreas and kidney transplantation is 87% at 1 year and 79% at 3 years [16]. For pancreas transplantation alone the rates were 79% at 1 year and 64% at 3 years. The reasons for the greater survival rates for simultaneous and pancreas and kidney transplantation are not clear, although this is the procedure most commonly used, and therefore, the most familiar. Another advantage of the combined procedure is that serum creatinine levels are used to monitor for early kidney rejection, which results in antirejection treatment that may also benefit the transplanted pancreas before manifest islet failure is apparent. When interpreting these data, it is important to remember that none of the patients were assigned to transplant categories on a randomized basis and that the data cited came from multiple transplant centers with varying degrees of experience.

Autoislets

Autoislet transplantation was originated at the University of Minnesota where the first procedure was carried out in 1980 [17]. Overall, the recipients have usually been adults, female, and nondiabetic at the time of pancreatecomy. The etiologies have been 41% idiopathic, 17% pancreas divisum, 14% genetic, 9% related to abnormalities involving the sphincter of Odi, and 7% alcoholic [18]. More recently, children with pancreatitis are undergoing this procedure [19]. By the mid-90s it was reported by this group that a minimum of 300,000 islets was required to achieve normoglycemia and insulin-independence in 74% of recipients for >2 years [20]. Many more centers have

more recently accelerated their autoislet transplant programs and are reporting outcomes similar to those published by the University of Minnesota [21–28].

Alloislets

The most extensive single center experience with alloislets has been that of the Edmonton group from the University of Alberta. Their initial publication in 2000 demonstrating a 100% success rate in 7 patients receiving islets from an average of two donated pancreases with avoidance of corticosteroid treatment in the immunosuppression regimen [29] sparked great interest. Although the initial successes were largely confirmed from their 2 year post-transplant report, by 5 years enthusiasm for the procedure had diminished because by 15 months post-transplant 50% of the recipients had returned to insulin [30]. The 5-year outcomes revealed a 15% failure rate, a 77% partial success rate, and an 8% complete success rate [30] (Figure 52.2). Subsequent reports from collaborative studies and single centers using the Edmonton protocol have reported data that are similar to that published by the Edmonton group [31–36]. The Collaborative Islet Transplant Registry (CITR) Sixth Annual Report of November 1, 2009 [14] indicates improvement in success rates in achieving insulin independence (70% at 1 year post-transplant, 55% at 2 years, and 36% at 4 years). With increasing frequency publications have appeared from single centers reporting improved islet survival rates and use of singe-donor alloislet grafts [37,38].

Clinical outcomes on diabetes complications after successful pancreas and alloislet transplantation

Beta-cell function
Pancreas
The major metabolic defect to overcome in patients with T1DM is the total absence of insulin secretion. Their β cells
Figure 52.2 Comparison of hemoglobin A1c levels after successful alloislet transplantation pre-transplant and up to 5 years post-transplant. Source: Ryan 2005 [30]. Reproduced with permission of American Diabetes Association.

have been killed by the autoimmune process that underlies this disease. Although exogenous insulin therapy has been remarkably effective in maintaining the life of such patients, it is extremely difficult, if not impossible, to maintain 24-hourly normal glucose levels using insulin-based therapy. In contrast, successful pancreas transplantation is remarkably effective in restoring endogenous insulin secretion, independence from exogenous insulin therapy, normal glucose levels, and normal hemoglobin A1c levels [39]. Normalization of fasting blood glucose levels has been documented to exceed several decades. That not only fasting but also postprandial glucose levels are improved can be appreciated when hemoglobin A1c levels in pancreas transplant recipients are compared to those observed in the Diabetes Control and Complications Trial (DCCT). Patients undergoing standard therapy in the DCCT had an average hemoglobin A1c value of approximately 9% whereas those undergoing intensive insulin-based management had an average level of approximately 7%. In a group of successful pancreas transplant recipients followed over 6 years, the average hemoglobin A1c level ranged between 5% and 6% [40].

Alloislets
Using a circulating C-peptide level of >0.3 ng mL^{-1} as indicative of graft function, CITR reports C-peptide positivity in 72% of recipients at 1 year and 41% at 4 years post-transplant [14]. HbA1c levels <6.5% and absence of severe hypoglycemia was reported as 2% pre-transplant, 51–65% at one year post-transplant, and 20–45% at 4 years post-transplant. Restoration of β-cell function by measurements of insulin secretion has been well documented [41,42].

Alpha-cell function
Pancreas
Hypoglycemia is one of the major limitations to obtaining optimal hemoglobin A1c levels when using intensive insulin-based management. In nondiabetic individuals, glucagon secretion from the pancreatic α cell occurs promptly when glucose levels fall to approximately 65 mg dL^{-1}. Glucagon released from the α cell immediately enters the hepatic portal circulation through which it travels to the liver to stimulate glycogenolysis. This promptly releases glucose into the hepatic vein and thereafter into the general circulation. Soon after the glucagon response, the adrenal medulla releases epinephrine, which also stimulates hepatic glycogenolysis. Typically, patients who have had T1DM for greater than 5 years have absent glucagon responses, and after 10 years have diminished epinephrine responses, to hypoglycemia. To make matters worse, patients who are recurrently hypoglycemic do not have the usual array of physical symptoms—warmth, sweating, visual disturbances, rapid heart rate, and tremulousness—that accompany hypoglycemia. Because these warning signs are absent, patients often do not realize they are hypoglycemic until blood glucose levels drop as low as 30 mg dL^{-1}, an obviously dangerous situation because

obtundation and even death may follow as values drop even lower. The loss of symptomatic responsiveness to hypoglycemia has been shown to be an example of desensitization since loosening of tight metabolic control with insulin in type 1 diabetic patients is accompanied by a return of symptoms to subsequent hypoglycemia [43].

Successful pancreas transplantation completely restores endogenous glucagon secretion to hypoglycemia (Figure 52.3). Hypoglycemic, hyperinsulinemic clamps, have shown that transplanted patients have virtually identical glucagon responses to those observed in nondiabetic control subjects [44]. Benefits are also observed for epinephrine secretion (Figure 52.4), although this response is not completely restored. As far as the patient is concerned, the most salutary improvement is the complete return of symptom responses during hypoglycemia (Figure 52.4). No differences are found in symptomatology at the various glucose levels developed during a hypoglycemic clamp when comparing transplanted patients to normal controls and both groups have markedly more intense symptoms than nontransplanted type 1 diabetic patients [44].

Alloislets

A peculiarity of transplanting islets into the intrahepatic site is that they fail to secrete glucagon in response to hypoglycemia, although they respond normally to intravenous arginine [45] (Figure 52.5). On the other hand, islets transplanted into nonhepatic sites, such as the intraperitoneal cavity, omentum, serosal surfaces of bowel, and spleen respond to hypoglycemia normally [46]. In essence, this implies that the decreased prevalence of insulin-induced hypoglycemia in alloislet recipients cannot be attributed to improved glucagon secretion and associated improvements in hormonal counterregulation of

Figure 52.4 Epinephrine and symptom score responses during hypoglycemic clamps in untransplanted patients with type 1 diabetes mellitus (T1), type 1 diabetic pancreas transplant (P) recipients, nondiabetic kidney transplant (K) recipients, and control (C) subjects. Epinephrine is secreted and symptom responses are present during the hypoglycemic clamp procedure in all groups but they are significantly depressed in patients with IDDM. Pancreas transplantation in IDDM recipients partially restores the defective epinephrine response and completely restores the symptom response. Source: Kendall et al. 1997 [44].
Figure 52.5 Lack of glucagon responsiveness to hypoglycemic in successful recipients of alloislets. Source: Paty et al. 2002 [45].

hypoglycemia. This again raises the question whether improved medical management of insulin-based therapy post-transplant might be playing a role in this favorable outcome of the alloislet transplant. The data in this area also raise the issue whether nonhepatic sites alone or in addition to the hepatic site should be used for alloislet and autoislet islet transplantation to provide glucagon responsiveness to hypoglycemia, something the α cells in the native pancreas of T1DM recipients are unable to do because of the absence of contiguous β-cell counterregulation of α-cell function.

Nephropathy
Pancreas

Renal disease is a major secondary complication of chronic hyperglycemia. Decreased glomerular filtration rate and
Figure 52.3 Comparison of glucagon responses during hypoglycemic clamps in patients with insulin-dependent diabetes mellitus (IDDM), patients with successful pancreas transplantation (PTx), and control subjects. After successful pancreas transplantation the glucagon responses are indistinguishable from those of control patients whereas responses in patients with IDDM are absent. Source: Kendall et al. 1997 [44].

Pre-transplant   5 yrs Post-transplant   10 yrs Post-transplant

Figure 52.6 Comparison of kidney biopsies of native pancreas in type 1 diabetic recipients of pancreas transplantation before, 5 years, and 10 years post-transplant. The increased basement membrane thickness and increased mesangium characteristic of type 1 diabetes that was present pre-transplant was still present at 5 years post-transplant but greatly decreased at 10 years post-transplant. Source: Adapted from Fioretto 1998 [46]. Reproduced with permission of Massachusetts Medical Society. (For a color version of this figure, please see color plate section.)

mesangial thickening are commonly observed as diabetes progresses. Normal kidneys transplanted into diabetic patients who remain hyperglycemic soon undergo the same deterioration in structure and function experienced by native kidneys. In cases of simultaneous pancreas and kidney transplantation, transplanted kidneys fare much better because the recipients become euglycemic. Abnormal diabetic renal structure in the native kidney undergoes resolution of thickened basement membranes and mesangial accumulation after 10 years of normal glucose levels following successful pancreas transplantation [47] (Figure 52.6).

Alloislets

As yet, there have been no large series of studies of the effect of successful alloislet transplants on diabetic nephropathy. This should not be surprising since it took a 10-year prospective study [47] to demonstrate beneficial effects of pancreas transplantation on basal membrane thickness and mesangial volume. Preliminary reports of beneficial effects on renal function have appeared, as noted by Fiorina et al. [47].

Neuropathy

Motor and sensory neuropathies greatly diminish the quality of life in patients with chronic diabetes. Sensory neuropathy can be expressed as chronic numbness of the skin, particularly in the feet, and can also be expressed as chronic pain and exquisite sensitivity to touch. After several years of successful pancreas transplantation and return to euglycemia, indices of sensory and motor nerve function are stabilized. It has been demonstrated

that parameters of nerve function including physical exam, motor and sensory nerve conduction, and cardiorespiratory reflexes can be stabilized for up to 10 years in successful recipients [49]. Even more impressively, the marked diminution in life expectancy that accompanies autonomic dysfunction in chronic diabetes, which approximates 50% at 5 years, is greatly improved. In one study, a group of type 1 diabetic patients with autonomic insufficiency who had successful pancreas transplantation and return to euglycemia had a 20% mortality at 5 years versus an approximate 70% mortality in failed pancreas transplant recipients [50].

Alloislets

As yet, there have been no large series of studies of the effect of successful alloislet transplants on diabetic neuropathy. Preliminary reports of beneficial effects on function have appeared, as noted by Fiorina et al. [47].

Retinopathy
Pancreas

The impact of successful pancreas transplantation on retinopathy has been equivocal. Several studies comparing transplanted to nontransplanted patients with chronic diabetes have indicated no significant differences in abnormal retinal changes. This generally gloomy conclusion was more recently challenged by a report indicating that less laser therapy for retinopathy was required in patients undergoing pancreas and kidney transplantation compared to those undergoing kidney transplantation alone [51].

Alloislets

As yet, there have been no large series of studies of the effect of successful alloislet transplants on diabetic retinopathy. Preliminary reports of beneficial effects on eyes have appeared, as noted by Fiorina et al. [47].

Macrovascular disease

Initially, there was no indication that macrovascular disease in patients with diabetes may be improved by a return to hypoglycemia following pancreas transplantation. Concern existed that the hyperinsulinism that is caused by systemic venous drainage of the transplanted pancreas may be harmful in terms of accelerating atherosclerosis. However, if anything, circulating lipids are under better control following pancreas transplantation and there have been no reports of accelerated atherosclerosis in transplant recipients. To the contrary, three fairly recent reports suggest that successful pancreas transplant recipients have improved vascular status. Two studies involved examination of intima media thickness of the carotid artery. In one report, thickness was significantly less in patients who had undergone pancreas and kidney transplantation compared to patients undergoing kidney transplantation alone [52]. In the second study, carotid intima media thickness 4 years after successful pancreas transplantation was no different than that found in a nondiabetic control group, but was less than that found in a pre-pancreas transplant diabetic group [53]. However, both studies were cross-sectional and did not obtain paired measures in the same patients before and after pancreas transplantation. On the other hand, a study of coronary artery patency indicated less narrowing over time in a group of successful pancreas transplant patients studied prospectively compared to a group of patients who failed transplantation [54].

Alloislets

As yet, there have been no large series of studies of the effect of successful alloislet transplants on macrovacular disease. Preliminary reports of beneficial effects on vessels have appeared, as noted by Fiorina et al. [47].

Quality of life

Studies consistently demonstrate benefits for successful recipients of pancreas and auto- and alloislet transplantation. Although this outcome is the most clinically difficult to objectively measure, it is clearly the most important indicator of success or failure.

Pancreas

Virtually all published studies report that the quality of life after pancreas transplantation improves regardless of whether a kidney transplant is involved or not [55]. The most common question asked is whether the recipients would prefer a successfully transplanted organ and the risks of chronic immunosuppression or a return to their original diabetic state and insulin-based therapy with the hazards of hypoglycemia.

Patients usually report they prefer taking immunosuppressive drugs as the price of a functioning pancreas, normal glucose levels, and decreased risk of developing secondary complications of diabetes, including hypoglycemia. An important caveat is that most diabetic patients who receive transplants have had serious difficulty avoiding extremely high and low glucose levels. Clearly, the worse the quality of life before transplantation, the more likely it is to improve after successful surgery.

Autoislets

Relief from pain in autoislet recipients (improvement or complete resolution) is reported by 80–86% of recipients at 6 months to 3 years after surgery and half have withdrawn completely from narcotics used pre-operatively [18]. Quality of life has generally improved, although not infrequently patients continue to have bouts of abdominal pain that are different in nature than the pain they associated with chronic pancreatitis. This pain is usually ascribed to temporary episodes of partial bowel obstruction secondary to intra-abdominal adhesions. One might expect recipients of intrahepatic autoislets to have difficulties with hypoglycemia because some use long-acting insulin and they have only partially functional intrahepatic α cells. However, the scientific literature is silent in this regard.

Alloislets

The main indication for alloislet transplantation is recurrent hypoglycemia secondary to exogenous insulin treatment. Using this measure, alloislet transplantation has been reported to be very successful [56,57]. Severe hypoglycemic events were reported by the 2009 CITR report [14] as 81% pre-transplant, and <10% by 4 years post-transplant. CITR also notes that even after complete graft failure there is enduring protection against severe hypoglycemia. This phenomenon has not yet been explained but raises the possibility that more sophisticated insulin-based management associated with transplant centers, independent of the success of alloislet grafts, contributes significantly to the lesser degrees of hypoglycemia encountered post-transplant compared to the pre-transplant situation.

Hypoglycemia and other complications of insulin therapy

Stephanie A. Amiel

King's College London and King's College Hospital, London, UK

Key points

- Hypoglycemia is common in insulin therapy for type 1 and late (insulin-deficient) type 2 diabetes.
- It results from excess insulin action plus defects in the body's usual counterregulatory mechanisms.
- Loss of subjective awareness of hypoglycemia increases the risk of severe episodes, with loss of cognitive function and ability to self-treat, 6- to 17-fold.
- Exposure to hypoglycemia induces defects in the normal defenses against hypoglycemia which can be restored by hypoglycemia avoidance.
- Fear of hypoglycemia is a major barrier to achieving good glycemic control and quality of life.
- Weight gain with insulin therapy is multifactorial but can be a barrier to patient compliance with therapy.
- Other complications of insulin therapy include local reactions at injection sites and rare cases of local or systemic insulin allergy.

Introduction

Hypoglycemia—low blood glucose—is the most important acute complication of glucose-lowering therapies. Hypoglycemia—and fear of hypoglycemia—limits attempts to achieve normoglycemia by pharmacologic therapies in people with diabetes and thus limits the ability to reduce the incidence of both micro- and macrovascular complications through normalized blood glucose control. In health, hypoglycemia only occurs in extreme circumstances, such as after extreme sport. In diabetes, hypoglycemia is common but its true prevalence varies widely, according to how it is defined and the clinical circumstances of the person's diabetes and its management.

Other associations of insulin therapy include failure to achieve optimized glucose control, weight gain, problems at the site of injection, rare local and very rare systemic insulin allergy. The list is short, as exogenous insulin is a (fairly) natural product and insulin therapy is effectively replacement of the missing hormone.

Definition of hypoglycemia

Surprisingly, definition of what constitutes hypoglycemia remains controversial. Hypoglycemia may be defined clinically, in terms of a syndrome associated with the low blood glucose concentration, or biochemically, as a quantitative blood (or plasma) glucose concentration below normal.

The American Diabetes Association (ADA) recently reviewed its descriptions of hypoglycemia [1]. Clinically, it describes five hypoglycemia syndromes, based on the severity of the clinical picture. Thus *severe hypoglycemia* is defined as that requiring assistance of another person to treat the hypoglycemia, implying that the plasma glucose has fallen too low to sustain normal cortical (intellectual) function, and the person is too incapacitated to recognize the situation and/or treat it themselves by eating. No defining glucose concentration is given. This definition may be too loose for young children, who will always need help treating a hypoglycemic event, and subcategorization into episodes involving unconsciousness, coma or seizure, and episodes requiring parenteral therapy (intramuscular glucagon or intravenous glucose) is added. Some authorities, particularly those working with children, require one or other or both of these events to be present to define severe hypoglycemia (e.g. [2]). Severe hypoglycemia is thought to occur at rates of 115 to 320 per 100 patient-years in adults with type 1, and 35 to 70 episodes per 100 patient-years in T2DM [3,4].

Mild hypoglycemia describes episodes in which the patient perceives symptoms compatible with hypoglycemia (see later) and self-treats by eating, associated with a measured low

plasma or blood glucose concentration. In the ADA document, this category is missing, effectively replaced by *documented symptomatic hypoglycemia*, which is described as the experience of "typical" hypoglycemia symptoms, in the presence of a measured low glucose concentration, the definition of which is discussed later. Self-management is implied, as need for assistance results in a definition of severe hypoglycemia. Some authorities also recognize *moderate hypoglycemia* in which the patient is aware and self-treats but the episode includes significant disruption to current activity. This can be useful in quantitating hypoglycemia experience, for example in research studies, but is necessarily subjective. *Asymptomatic hypoglycemia* is an episode in which plasma glucose is measured as low but for which the patient has no subjective awareness. Clinically, this is diagnosed when a patient is testing his or her blood glucose coincidentally, for example before a meal or an insulin dose, and finds it to be unexpectedly below normal. Asymptomatic hypoglycemia is also diagnosed when someone other than the patient first notices the hypoglycemia, as signs of hypoglycemia are manifested in the absence of any subjective awareness. Regular experience of asymptomatic hypoglycemia is described as *impaired awareness of hypoglycemia* [5]. It affects about 20% of people with T1DM of more than 2 years' duration [6] and probably about 10% of people with late, insulin-requiring T2DM [7]. It is important to diagnose, as it increases risk of a severe hypoglycemia sixfold in T1, and perhaps by as much as 17-fold in T2DM [7], an increase that may be driven by lower background risk in the aware and the older age and increased number of comorbidities likely to be found in people with insulin-deficient T2.

The ADA goes on to define *probable hypoglycemia* as episodes in which a patient experiences typical symptoms of hypoglycemia and recovers on self-administering glucose, but for which no confirmatory blood test is available. *Pseudohypoglycemia* is used to describe episodes in which a patient experiences hypoglycemic symptoms but a measured blood test shows unequivocal absence of hypoglycemia, with the plasma glucose concentration either in or above the normal range. The plasma glucose each individual responds to is greatly influenced by that person's recent glycemic experience and pseudohypoglycemia is typically seen in people accustomed to running high blood glucose concentrations and in "poor" diabetic control. This phenomenon has in the past been called *relative hypoglycemia*, which is perhaps less pejorative.

The aforementioned descriptions are generally accepted and differences in emphases with other classifications are minor. The biochemical definition of hypoglycemia is, however, more controversial. Many text books define the range of normal plasma glucose as between 3.5 and $7\,\text{mmol}\,\text{L}^{-1}$ (63–$126\,\text{mg}\,\text{dL}^{-1}$). This would allow us to define hypoglycemia as a plasma glucose of less than $3.5\,\text{mmol}\,\text{L}^{-1}$ ($63\,\text{mg}\,\text{dL}^{-1}$), a definition that has considerable clinical utility. During experimentally induced hypoglycemia, endogenous insulin secretion is reduced and glucagon release occurs at arterialized plasma glucose

concentrations of around $4\,\text{mmol}\,\text{L}^{-1}$ ($72\,\text{mg}\,\text{dL}^{-1}$) in healthy people, and because these responses may be diminished in a second experimental hypoglycemia after exposure to this value [8], the earlier referenced American publication defines a plasma glucose of $3.9\,\text{mmol}\,\text{L}^{-1}$ ($\leq 70\,\text{mg}\,\text{dL}^{-1}$) as hypoglycemia, making the occurrence of biochemical hypoglycemia much more common and limiting its utility as a predictor of severe hypoglycemia [9]. In people with insulin-deficient diabetes, the counterregulatory (protective) response to hypoglycemia does not include either reduction in circulating insulin or increase in pancreatic glucagon release, so the clinical relevance of a definition of hypoglycemia at $3.9\,\text{mmol}\,\text{L}^{-1}$ is doubtful. Most programs training patients in insulin use set a lower limit of the desirable glucose targets the patient should be trying to achieve as $>3.9\,\text{mmol}\,\text{L}^{-1}$ (usually $4\,\text{mmol}\,\text{L}^{-1}$ or higher), so defining $\leq 3.9\,\text{mmol}\,\text{L}^{-1}$ as an indication to eat to *avoid* hypoglycemia is universally accepted. Indeed the ADA document refers to this value as an "alert value" while continuing to espouse its use as a definition of hypoglycemia also [1]. Others prefer the clinically unequivocal value of $<3.5\,\text{mmol}\,\text{L}^{-1}$. This definition is supported for children, in a guideline written under the umbrella of the International Society for Pediatric and Adolescent Diabetes (ISPAD) in 2009. This describes plasma glucose concentrations between 3.3 and $3.9\,\text{mmol}\,\text{L}^{-1}$ (59 and $70\,\text{mg}\,\text{dL}^{-1}$) as placing a child at risk of severe hypoglycemia and supports as usual use a cut-off for defining hypoglycemia as $<3.6\,\text{mmol}\,\text{L}$ ($65\,\text{mg}\,\text{dL}^{-1}$), adding a rider that $3.9\,\text{mmol}\,\text{L}^{-1}$ should be used as the lowest end of any desirable target range to keep in line with the ADA guidance [10]. This advice reinforces the clinical importance of separating out true hypoglycemia, and setting a lower limit for an optimal target range, which should be higher.

Although severe hypoglycemia is almost invariably defined clinically, a plasma glucose value of $<3\,\text{mmol}\,\text{L}^{-1}$ ($54\,\text{mg}\,\text{dL}^{-1}$) (the arterialized plasma glucose concentration at which cognitive function is detectable [11]), is sometimes used to define clinically important hypoglycemia, and failure to perceive symptoms when a home blood glucose test is below $3\,\text{mmol}\,\text{L}^{-1}$ is sometimes taken as an indicator of impaired awareness [12]. This definition avoids over-diagnosing impaired awareness of hypoglycemia, which has impact on people's personal freedoms (see later). In children, it has been recommended to define asymptomatic hypoglycemia if the child has no symptoms under $3.6\,\text{mmol}\,\text{L}^{-1}$ ($65\,\text{gm}\,\text{dL}^{-1}$) [10].

Definitions are further complicated by the fact that plasma glucose concentrations are, on average, 10% higher than whole blood glucose concentrations, as red cells occupy space, and venous blood will have a lower glucose concentration than arterial, because glucose will have been removed by metabolically active tissue. Home blood glucose monitoring uses finger prick blood glucose but meters are generally calibrated to plasma glucose values. The error range on many home blood glucose monitoring systems may also be large. New guidelines from the International Organization for Standardization (ISO) will require 99% of readings in the range $4.2\,\text{mmol}\,\text{L}^{-1}$

(75 mg dL^{-1}) or higher to be within 15% of the reference range, and readings less than this value should not differ from the reference range by more than 0.83 mmol L^{-1} (15 mg dL^{-1}) [13]. Many currently commercially available systems struggle to reach these constraints, even when quality control is optimized [14].

Using interstitial glucose measurement to diagnose hypoglycemia is also not simple. "Continuous glucose monitoring" (CGM) from sensors placed in the subcutaneous tissue is calibrated to finger-prick glucose measurements, which are generally calibrated to plasma glucose equivalents. The CGM readings may lag behind or run ahead of plasma glucose, especially when its concentration is changing rapidly, by as much as 20 min [15]. For robust detection of clinically important hypoglycemia, CGM values of <3 mmol L^{-1}, or even <2.2 mmol L^{-1} have been used [3]. In line with the earlier point about the difference between diagnosing true hypoglycemia and detecting a glucose concentration at which action should be taken to prevent hypoglycemia, care should be taken to set targets for alarms for hypoglycemia when using real-time CGM, to strike the right balance between too many false positives and achieving hypoglycemia protection. While the literature has suggested using 4 mmol L^{-1} as an alarm threshold for hypoglycemia, our clinical practice is to start at 3.5 mmol L^{-1}, adjusting the value according to patient characteristics.

Physiologic responses to hypoglycemia

The brain requires a constant supply of oxygen and glucose, depending on a well-sustained blood flow with an adequate plasma glucose concentration. Equally, high plasma glucose has pathologic effects. The body has a sophisticated system of glucose control which is deranged in diabetes (Figure 53.1(a)).

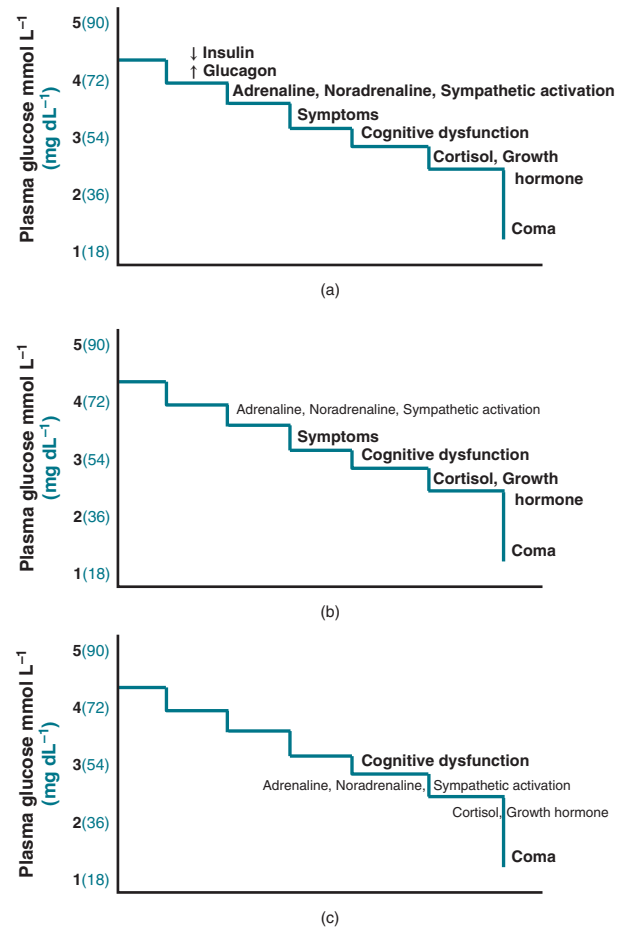
Circulating glucose concentrations are determined by the rate of glucose entering the circulation from endogenous stores in the liver and to some extent kidney, and by consumption and digestion of carbohydrate in eating and drinking, balanced by the rate at which glucose is removed from the circulation by metabolically active tissue. Control of energy balance is complex, beyond the scope of this chapter, but much of it occurs centrally, in the brain, which detects a falling glucose supply by changes in activation of glucose-sensing neurons, concentrated in brain regions such as the ventromedial hypothalamus (reviewed in [16]). The response to a threatened glucose lack is a stress response but includes first a pancreatic response with reduced insulin secretion and enhanced glucagon release, de-repressing and stimulating glycolysis and endogenous glucose production to arrest the plasma glucose fall. In studies where experimental hypoglycemia has been induced by insulin infusion (often with glucose infusion to control the hypoglycemia) this happens at an arterialized plasma glucose of around 3.8 mmol L^{-1} (68 mg dL^{-1}) [17]. At a slightly lower glucose, the sympathetic nervous system is activated, adrenaline and noradrenaline concentrations rise in the circulation,


Figure 53.1 Schematic representation of counterregulatory neurohumoral response to hypoglycemia. (a) The nondiabetic response; (b) response in established T1DM with loss of ability to regulate circulating insulin response or mount a glucagon response to hypoglycemia and diminished peak catecholamine responses; (c) response in impaired hypoglycemia awareness, in which stress response onset is delayed to a lower glucose concentration and diminished at each glucose level, now starting after the onset of detectable cognitive impairment. further enhancing endogenous glucose production through glycogenolysis, supporting also gluconeogenesis, in part through enhanced supply of suitable precursors via lipolysis, associated with reduced rate of glucose uptake by peripheral tissues such as muscle and fat. Heart rate and stroke volume increase, and gastric emptying accelerates, with the effect of enhancing tissue and brain glucose supply. Should the glucose continue to fall, driven by continued availability of insulin, cortisol and growth hormone are released further to support gluconeogenesis and reduce peripheral glucose uptake. Clinical episodes of hypoglycemia result from excess insulin action, plus a failure of these counterregulatory mechanisms.

Symptoms of hypoglycemia are in part associated with the stress response. Sometimes termed *autonomic*, *neurogenic*, or *adrenergic*, they include sweating, palpitation, shaking, and hunger [18]. Associated signs include sweating, pallor, tremor,

tachycardia (or very occasionally bradycardia and arrhythmia), widening of the pulse pressure. Another group of symptoms are associated with reduced glucose supply to the brain and are termed *neuroglycopenic*. These include feeling drowsy, inability to concentrate, feeling confused, having difficulty speaking and in coordination. Associated signs are slurred speech, inappropriate behavior or emotional responses. When symptoms of hypoglycemia are classified by statistical means, three groups of symptoms are identified. In addition to those classically fitting the descriptions of autonomic and neuroglycopenic, a third group of symptoms including blurred vision, headache, and malaise are found [18]. Although neuroglycopenic symptoms probably occur at lower glucose concentrations than adrenergic symptoms, the important point clinically is that it is the patient who feels them. While the patient remains able to experience a symptom, recognize it as associated with hypoglycemia and respond by ingesting carbohydrate, the hypoglycemia is symptomatic and not severe. This remains true even though the patient may describe the episode as very severe, in the sense that he or she experienced very unpleasant and severe symptoms.

In children and the elderly, the clinical appearance of hypoglycemic events is different. In children, behavioral signs are common, and in young children may be the main indication [19]. Such behavioral signs include irritability, erratic behavior, nightmares, and inconsolable crying [10]. In the elderly, at least in people with T2DM, a group of neurologic symptoms associated with coordination and articulation are described [20].

Defects in counterregulation associated with diabetes treatments

The treatment of insulin-deficient diabetes is artificial elevation of circulating insulin concentrations by subcutaneous administration of exogenous insulin, which reverses the gradient between the concentration in the hepatic portal vein and that in the peripheral circulation. A degree of peripheral hyperinsulinemia is required to approach normal hepatic insulinization, which may enhance hypoglycemia risk. When insulin secretagogues (sulfonylureas, meglitinides) are used, this is less of a problem but with both forms of therapy the important point is that the circulating insulin concentrations are no longer under endogenous control and remain elevated even if plasma glucose is falling (Figure 53.1(b)). It has also been shown that people with insulin-deficient diabetes do not mount a glucagon response to hypoglycemia [21]. This appears at least in part to be because of loss of an as yet unidentified signal between the β cell and the α cell—if insulin secretion is maintained during hypoglycemia, for example by sulfonylurea induction of the hypoglycemia, the α cell is not responsive to the hypoglycemia [22]. People with insulin-deficient T2DM show a similar defect in glucagon responses to hypoglycemia as described in T1DM [23]. If exogenous insulin is infused via an intraperitoneal route (when about half will be absorbed into the portal circulation), glucagon responsiveness to hypoglycemia may be better maintained.

Loss of both insulin and glucagon responses to hypoglycemia renders the diabetic person dependent on the rest of the stress response and most importantly the symptomatic response as defense against hypoglycemia profound enough to cause cognitive impairment and confusion (Figure 53.1(b)). It is clinically important—loss of C-peptide, indicating more profound loss of endogenous insulin, is an important risk factor for severe hypoglycemia and even imperfect insulin secretory function after islet transplantation provides protection against severe hypoglycemia [24,25]. In the Diabetes Control and Complications Trial in people with T1DM randomized to intensive therapy, absence of measurable C-peptide before or during the first 6 years of the study was associated with higher rates of severe hypoglycemia, illustrating the importance either of C-peptide itself in defense against hypoglycemia by some mechanisms as yet unknown or as an indicator of more complete loss of endogenous insulin with no ability to reduce hepatic exposure to insulin as circulating glucose concentrations fall, and an associated loss of glucagon responses [23]. While there are many data supporting the link between loss of C-peptide and severe hypoglycemia risk, one recent small study has described defective glucagon responses in young people newly diagnosed with T1DM who retained C-peptide responses to a mixed meal, so the impaired glucagon responses may be multifactorial [26]. With increasing diabetes duration, further defects develop, with evidence for impairment of catecholamine responses to hypoglycemia in people with long duration diabetes (over 15 years) [21]. However, about 75% of people retain subjective awareness of hypoglycemia, highlighting that subjective awareness is associated with but not wholly dependent upon the stress hormone responses [27].

Associated with the stress hormone response there are other acute responses to a hypoglycemic episode. Metabolic responses include a fall in plasma potassium. There is an inflammatory response, with release of inflammatory cytokines and circulating clotting factors increase [28]. As described earlier, heart rate and stroke volume increase; brain blood flow rises; gastric emptying accelerates.

Hypoglycemia during sleep at night may not be associated with any counterrregulatory response [29].

Impaired awareness of hypoglycemia

As reported earlier, impaired hypoglycemia is associated with a 6- to 17-fold increase in severe hypoglycemia. Loss of awareness of hypoglycemia affects approximately 20% of adults with T1DM of more than 2 years' duration [6], and is likely to increase in prevalence with increasing duration [27]. It has been described in children, with just over 20% of one sample identified as having impaired awareness, robustly identified but including occurrence of severe hypoglycemia in the definition.

In an audit of a UK program of structured education in flexible insulin therapy for adults with T1DM, with a mean duration of diabetes of 18 years, 40% reported not feeling symptoms of hypoglycemia until their glucose was under 3 mmol L^{-1} or not perceiving symptoms at all [12]. This probably reflects both the long duration of diabetes in people coming for the training program and a preferential referral of people with problematic hypoglycemia. Parenthetically, 1 year after training in flexible insulin therapy, 43% of those reporting impaired awareness at baseline had recovered awareness, although a small number of people also reported new reduced awareness. Overall the rate of impaired awareness fell from 40 to 33% [12].

Loss of subjective awareness of hypoglycemia is associated with a failure of the counterregulatory responses to hypoglycemia, as measured in an experimental setting (Figure 53.1(c)). People with impaired hypoglycemia awareness failed to arrest the glucose fall in response to low-dose insulin infusion, and this failure, and the lack of symptoms, was not associated with classical diabetic autonomic neuropathy [30]. Failure to counterregulate in response to low-dose insulin infusion was found to predict risk of severe hypoglycemia during subsequent intensification of insulin therapy [31]. Disappointingly, intensified therapy did not restore defective glucagon responses to hypoglycemia and indeed impaired adrenaline responses seemed to be induced by the tightening of glycemic control [32]. Clinically, it had been noted that people using the then new insulin pump therapy were "tolerating" hypoglycemia better than when using conventional injection therapy with looser diabetes control.

Using intensified insulin therapy as a model, loss of subjective awareness of hypoglycemia was shown to be associated not only with inability adequately to arrest a glucose fall during low-dose insulin infusion [33], but also to be associated with impaired counterregulatory hormone responses to a fixed stepped hypoglycemic challenge [34]. Catecholamine responses and symptoms occurred at lower glucose concentrations and were diminished at any given glucose concentration in people using intensified insulin therapy (Figure 53.2). The patients were also experiencing more frequent hypoglycemia in daily life. Similar defects in counterregulation were later shown to be inducible in hypoglycemia naïve healthy volunteers and in people with T1DM by antecedent exposure to hypoglycemia [35]. Surprisingly, quite modest exposure was required to induce the defect—2 hours at 3 mmol L^{-1} in the afternoon following a controlled stepped reduction in arterialized plasma glucose to 2.8 mmol L^{-1} was enough significantly to impair adrenaline, glucagon, cortisol, and symptomatic responses to a repeated stepped hypoglycemic challenge the next day. Later studies found that 30 min at 3 mmol L^{-1} was enough to reduce symptomatic responses [36]. Similar data have been found in people with diabetes. *Nocturnal hypoglycemia can create defective awareness of hypoglycemia the next day*.

Experimentally, impaired hypoglycemia awareness, and in most studies, counterregulatory responses, can be restored by
Figure 53.2 Data from two studies showing (i) the diminution and delay of the adrenaline response to controlled hypoglycemia before and after increased exposure to hypoglycemia, in this case by intensification of insulin therapy as then practiced, and (ii) a superimposition of the glucose concentration at which cognitive dysfunction, detected by impaired performance of the four-choice reaction time (4CRT), was first detected during a similar cross-sectional study of people with and without impaired hypoglycemia awareness. Source: Maran 1995 [11] and Amiel 1988 [34].

careful avoidance of hypoglycemia in daily life [37]. In studies done in the time before online glucose sensing, hypoglycemia of <3 mmol L^{-1} on intermittent home blood glucose monitoring was avoided for at least 3 weeks to restore responses not just in people with long duration tightly controlled T1DM and impaired hypoglycemia awareness but also in people with poorly controlled T1DM and intermittent severe hypoglycemia. In practice, such avoidance can be difficult for patients to maintain (Figure 53.3) (see restoration of awareness).

The brain's responses to hypoglycemia

Glucose sensing systems are found in the brain and in the hepatic portal vein, monitoring glucose supply to the brain and glucose entry from the gastrointestinal tract. In preclinical studies, prolonged exposure to hypoglycemia was associated with an upregulation of brain glucose uptake [38,39]. In human volunteers, brain glucose uptake measured by the Kety-Schmidt arteriovenous difference technique was increased during hypoglycemia after 58 hours' exposure to circulating glucose concentrations of 2.9 mmol L^{-1} or 52 mg dL^{-1} (except after meals) and in people with intensively treated T1DM [40,41]. The hypothesis was that hypoglycemia induced an upregulation of brain glucose transport such that brain glucose concentrations might be better maintained in subsequent episodes, so the hypoglycemia was not noticed and no stress response mounted. Yet clinically, onset of cognitive dysfunction in hypoglycemia occurs at glucose

concentrations no different from or only slightly lower than usual in people with delayed onset of counterregulation, suggesting that any similar mechanism in hypoglycemia exposure in insulin therapy in man is not global. Human neuroimaging studies have failed to show altered glucose uptake in people exposed to different blood glucose concentrations (e.g. [42,43]).

Rodent studies showed networks of neurons in the basal ganglia and hypothalamus activated by glucoprivation. Lowering glucose in the ventromedial hypothalamus initiated a hyperglycemic stress response, with little response to systemic hypoglycemia if glucose concentrations were maintained there. In human neuroimaging studies, changes in perfusion of the hypothalamus have been demonstrated as plasma glucose was lowered to $4.3 \, \text{mmol L}^{-1}$ ($77.2 +/- 2 \, \text{mg dL}^{-1}$), prior to the measurable release of catecholamines. In healthy people, an evolution of regional brain activation has been described, involving thalamus, anterior cingulate cortex, the hypothalamic pituitary axis, and prefrontal regions (Figure 53.4) [44]. When comparing people with T1DM with and without impaired awareness of hypoglycemia, reduced activation of brain regions involved in interoception (perception of the body's internal state); sympathetic responses and stress responses is seen, but also altered responses in prefrontal brain regions involved in reward pathways and hedonic perception [45].

Various experimental protocols have been used to investigate further the pathogenesis of impaired awareness of hypoglycemia, seeking evidence to inform a treatment that might restore the impaired defenses against subsequent hypoglycemic

Figure 53.4 Statistical parametric maps superimposed on MR brain images, showing evolution of changes in regional brain blood flow during experimentally induced hypoglycemia and recovery using water positron emission tomography in healthy volunteers. Blood flow increased (orange) in brain regions involved in stress response, including hypothalamus and pituitary, in symptom perception and awareness including anterior cingulate cortex and in prefrontal regions involved in reward pathways; decreasing (blue) in brain regions involved in balance and memory formation. In the posterior thalamus, flow increased in hypoglycemia and reduced during recovery, the latter perhaps associated with the drowsiness that follows hypoglycemia. Source: Teh et al. [44]. stimuli. Available evidence implicates dopaminergic pathways and opiate receptors [16]. It is hypothesized that brain glucose sensors use similar intracellular mechanisms to those of the pancreatic β cell to respond to changes in available glucose, with a fall in plasma glucose driving release of an inhibitory neuro-transmitter to de-repress the hyperglycemic stress responses, and there has been interest in seeing whether reagents that alter insulin secretion or opiate receptor pathways may also affect counterregulatory responses to hypoglycemia [16].

Risk for severe hypoglycemia

Apart from defective counterregulatory hormone responses associated with long duration diabetes and prior exposure to hypoglycemia, risk of hypoglycemia is increased by other factors that impair the counterregulatory response (Table 53.1). These include lack of endogenous glucose stores as may occur

Table 53.1 Factors increasing risk of hypoglycemia in insulin-treated diabetes

Non-remedial patient characteristics
      Age (under 5 or elderly)
      Diabetes duration
      Female gender
      C-peptide negativity
      Comorbidities and polypharmacy
      Enhanced insulin sensitivity of early pregnancy
Precipitants of individual events
      Insulin dose error
      Lower than anticipated carbohydrate intake
      Exercise[a]
      Alcohol excess[a]
      Massage or heating of injection site
      Co-incident use of recreational drugs
Prolongation of insulin action/reduced insulin clearance
      Exogenous insulin therapy
